<sup>2</sup>LanzaTech Inc., Skokie, IL, United States

Gas fermentation has emerged as a sustainable route to produce fuels and chemicals by recycling inexpensive one-carbon (C<sub>1</sub>) feedstocks from gaseous and solid waste using gas-fermenting microbes. Currently, acetogens that utilise the Wood-Ljungdahl pathway to convert carbon oxides (CO and CO<sub>2</sub>) into valuable products are the most advanced biocatalysts for gas fermentation. However, our understanding of the functionalities of the genes involved in the C<sub>1</sub>-fixing gene cluster and its closely-linked genes is incomplete. Here, we investigate the role of two genes with unclear functions—hypothetical protein (*hp*; LABRINI\_07945) and CooT nickel binding protein (*nbp*; LABRINI\_07950)—directly adjacent and expressed at similar levels to the C<sub>1</sub>-fixing gene cluster in the gas-fermenting model-acetogen *Clostridium autoethanogenum*. Targeted deletion of either the *hp* or *nbp* gene using CRISPR/nCas9, and phenotypic characterisation in heterotrophic and autotrophic batch and autotrophic bioreactor continuous cultures revealed significant growth defects and altered by-product profiles for both  $\Delta hp$  and  $\Delta nbp$  strains. Variable effects of gene deletion on autotrophic batch growth on rich or minimal media suggest that both genes affect the utilisation of complex nutrients. Autotrophic chemostat cultures showed lower acetate and ethanol production rates and higher carbon flux to CO<sub>2</sub> and biomass for both deletion strains. Additionally, proteome analysis revealed that disruption of either gene affects the expression of proteins of the C<sub>1</sub>-fixing gene cluster and ethanol synthesis pathways. Our work contributes to a better understanding of genotype-phenotype relationships in acetogens and offers engineering targets to improve carbon fixation efficiency in gas fermentation.

## 1 Introduction

The high concentration of greenhouse gases (GHG) in the atmosphere is leading to potentially irreversible climate change threatening Earth's sustainability. Fossil fuel combustion for energy, heat, and transportation is widely recognised as the primary source of GHG (mainly CO<sub>2</sub>) from human activities (Sixth Assessment Report IPCC, 2021). Likewise, increasing population leads to higher volume of generated waste [e.g., plastic waste and municipal solid waste (MSW)] that is negatively impacting ecosystems. Although decarbonising energy generation is important to lowering GHG emissions, we also need to adopt sustainable technologies for the production of fuels and chemicals as these will mostly stay carbon-based for the foreseeable future. The advancement of such technologies will be vital in achieving the United Nations Sustainable Development Goal (SDG) 7—Affordable and Clean Energy and SDG 13—Climate Action by the target year 2050.

Gas fermentation has emerged as an attractive route for sustainable production of low-carbon fuels and chemicals from gaseous one-carbon (C<sub>1</sub>) waste feedstocks (e.g., industrial waste gases (CO<sub>2</sub>, CO, and CH<sub>4</sub>) and syngas [from gasified biomass or MSW (CO, H<sub>2</sub>, and CO<sub>2</sub>)] using gas-fermenting microbes (Liew et al., 2016; Redl et al., 2017; Fackler et al., 2021; Pavan et al., 2022). Anaerobic acetogens are the most advanced biocatalysts for gas fermentation as they can naturally use gas as their sole energy and carbon source (Drake et al., 2006). Acetogens use the most energy-efficient CO<sub>2</sub> fixation pathway, the Wood-Ljungdahl pathway (WLP), to fix carbon oxides (CO<sub>2</sub> and/or CO) into many metabolic products via acetyl-CoA. Notably, the model-acetogen *Clostridium autoethanogenum* is being used as a commercial-scale cell factory for ethanol production (Köpke and Simpson, 2020) and has been demonstrated at pilot scale to produce two valuable industrial solvents: acetone and isopropanol (Liew et al., 2022).

The WLP is considered to be the first biochemical pathway on Earth (Russell & Martin, 2004) and it plays a vital role in global

carbon cycles by converting ~20% of CO<sub>2</sub> on Earth each year to billions of tons of acetate (Drake et al., 2006; Ljungdahl, 2009). The genes encoding the enzymes involved in the WLP belong to a large C<sub>1</sub>-fixing gene cluster (Figure 1) that has been annotated as CAETHG\_1606–1621 (Brown et al., 2014). The authors proposed that the cluster contains 16 genes, including the WLP central enzyme—the bifunctional CO dehydrogenase/acetyl-CoA synthase (CODH/ACS; CAETHG\_1620-21/1608) complex—that catalyses CO oxidation/CO<sub>2</sub> reduction and acetyl-CoA synthesis (Ragsdale and Pierce, 2008) and is essential for autotrophic growth (Liew et al., 2016). The cluster also encodes the pathway's most abundant but slowest enzyme in *C. autoethanogenum* (Valgepea et al., 2022): the formyl-THF ligase (Fhs; CAETHG\_1618). Though the biochemistry of the WLP is well-described (Ragsdale, 2008; Ragsdale and Pierce, 2008; Can et al., 2014), our understanding of the functionalities of genes within the proposed C<sub>1</sub>-fixing gene cluster is incomplete. For instance, functions of genes CAETHG\_1607 and 1613 are unclear in *C. autoethanogenum*. In fact, the C<sub>1</sub>-fixing gene cluster might be larger as several adjacent genes with unknown functions show similarly high gene and protein expression levels (Valgepea et al., 2017a-fixing gene cluster might be larger as several adjacent genes with unknown functions show similarly high gene and protein expression levels (Valgepea et al., 2017a-fixing gene cluster might be larger as several adjacent genes with unknown functions show similarly high gene and protein expression levels (Valgepea et al., 2017a; 2022). Two of such genes, found right downstream of the currently annotated cluster, are hypothetical protein (*hp*; CAETHG\_1604) and CooT family nickel binding protein (*nbp*; CAETHG\_1605). Both *nbp* and *hp* genes are

expressed highly in *C. autoethanogenum* and their homologs accompany the WLP genes of other commonly studied acetogens like *Clostridium ljungdahlii*, *Clostridium drakei*, *Clostridium carboxidivorans*, *Eubacterium limosum*, as well as thermophilic acetogens *Acetobacterium woodii* and *Thermoanaerobacter kivui*. Despite the clear genomic conservation of the *hp* and *nbp* genes among acetogens, their function has not yet been described. While nickel binding is predicted for Nbp based on gene sequence annotation, and histidine-rich amino acid sequence of the Hp protein suggests a metal-binding activity, the validity of these functional predictions remains to be demonstrated.

Determination of gene functionalities in acetogens through genotype-phenotype studies has been limited mostly due to slow, labour-intensive, and challenging workflows for constructing genetically modified strains (Pavan et al., 2022). However, gene-editing tools for acetogens have rapidly improved recently (Jin et al., 2020; Bourgade et al., 2021; Pavan et al., 2022). We thus aimed to take advantage of these developments to shed light on the functionalities of the *hp* (CAETHG\_1604) and the CooT family nickel binding gene *nbp* (CAETHG\_1605), referred to as LABRINI\_07945 for *hp* and LABRINI\_07950 for *nbp* based on the *C. autoethanogenum* base strain “Labrini” used in this work (Ingelman et al., 2023).

Here, we used CRISPR/nCas9 in *C. autoethanogenum* for the targeted deletion of two genes adjacent to the  $C_1$ -fixing gene cluster with unclear functions: named *hp* (LABRINI\_07945) and *nbp* (LABRINI\_07950). Phenotypic characterisation in heterotrophic and autotrophic batch and autotrophic bioreactor continuous cultures revealed significant growth defects and altered by-product profiles for both deletion strains compared to the base strain Labrini. Additionally, proteomics showed that disruption of either gene affects the expression of proteins of the  $C_1$ -fixing gene cluster and ethanol synthesis pathways. Our findings contribute to a better understanding of genotype-phenotype relationships which is needed to advance the metabolic engineering of acetogen factories for gas fermentation.

## 2 Materials and methods

### 2.1 Bacterial strains, growth media and cultivation conditions

A derivative of *C. autoethanogenum* DSM 10061 strain deposited in the German Collection of Microorganisms and Cell Cultures (DSMZ) named “Labrini” (Ingelman et al., 2023) was stored as a glycerol stock at  $-80^{\circ}\text{C}$  and used as the base strain for genetic engineering. *Escherichia coli* strains NEB Turbo and NEB Express (New England Biolabs) were used for cloning, plasmid assembly, and propagation. For transformant selection, the cultivation of *E. coli* was done in Lysogeny Broth (LB) medium supplemented with ampicillin (100  $\mu\text{g}/\text{mL}$ ).

For *C. autoethanogenum* cultivation on solid medium, YTF agar containing 10 g/L yeast extract (YE), 16 g/L tryptone, and 5 g/L fructose (Liew et al., 2017) was used and supplemented with 4  $\mu\text{g}/\text{mL}$  clarithromycin if needed (see below). For liquid batch cultures, cells were grown in chemically defined PETC-MES medium (Valgepea et al., 2017b) with or without YE (1.5 g/L) and supplemented with

0.4 g/L of cysteine-HCl-H<sub>2</sub>O as the reducing agent while the carbon source was either 5 g/L of fructose or syngas (50% CO, 20% H<sub>2</sub>, 20% CO<sub>2</sub>, and 10% Ar; AS Eesti AGA). The PETC-MES medium contained per litre: 1 g NH<sub>4</sub>Cl, 0.1 g KCl, 0.2 g MgSO<sub>4</sub>·7H<sub>2</sub>O, 0.2 g KH<sub>2</sub>PO<sub>4</sub>, 0.02 g CaCl<sub>2</sub>, 20 g 2-(N-morpholino) ethanesulfonic acid (MES), 0.25 g sodium acetate, 0.05 g Fe(SO<sub>4</sub>)·7H<sub>2</sub>O, 0.05 g nitrilotriacetic acid, 0.5 mL of 2 g/L resazurin, 10 mL trace metal solution (TMS) and 10 mL of Wolfe’s vitamin solution. The TMS solution contained per litre: 2 g nitrilotriacetic acid, 1 g MnSO<sub>4</sub>·H<sub>2</sub>O, 0.8 g Fe(SO<sub>4</sub>)·7H<sub>2</sub>O, 0.2 g CoCl<sub>2</sub>·6H<sub>2</sub>O, 0.2 mg ZnSO<sub>4</sub>·7H<sub>2</sub>O, 0.02 g CuCl<sub>2</sub>·2H<sub>2</sub>O, 0.02 g NaMoO<sub>4</sub>·2H<sub>2</sub>O, 0.03 g Na<sub>2</sub>SeO<sub>3</sub>·5H<sub>2</sub>O, 0.02 g NiCl<sub>2</sub>·6H<sub>2</sub>O and 0.02 g Na<sub>2</sub>WO<sub>4</sub>·2H<sub>2</sub>O. The Wolfe’s vitamin solution contained per litre: 2 mg biotin, 2 mg folic acid, 10 mg pyridoxine hydrochloride, 5 mg thiamine-HCl, 5 mg riboflavin, 5 mg nicotinic acid, 5 mg calcium pantothenate, 0.1 mg vitamin B<sub>12</sub>, 5 mg 4-aminobenzoic acid and 5 mg thioctic acid. The medium was prepared anaerobically, and the pH was adjusted to 5.7. Batch fermentations were performed in 250 mL Schott bottles with 50 mL liquid volume in biological triplicates incubated horizontally at 37°C with orbital shaking at 120 RPM under strictly anaerobic conditions unless stated otherwise. For autotrophic batch cultures, bottle headspace was pressurised to 140 kPa with syngas. Cultures were sampled during the exponential growth phase for growth characterisation and extracellular metabolome analysis to determine the maximum specific growth rate ( $\mu_{\text{max}}$ ) and production yields of acetate, ethanol, and 2,3-butanediol. At least five time points were used for  $\mu_{\text{max}}$  calculation resulting in correlation coefficients  $R^2 \geq 0.98$  between cultivation time and natural logarithm (ln) of the culture’s optical density (OD<sub>600</sub>). Product yields (mmol/gram of dry cell weight [DCW]) were estimated using at least three time points by linear regression between the respective product concentration (mmol/L) and biomass concentration (gDCW/L) with  $R^2 \geq 0.92$ . Product yields were estimated across time-points that showed no consumption of any of the three quantified products (i.e., products did not serve as substrates).

Continuous chemostat fermentations were carried out as described in detail before (Valgepea et al., 2017a). Shortly, all three *C. autoethanogenum* strains were grown in bioreactors on syngas under strictly anaerobic conditions at 37°C and pH 5 in chemically defined medium (without YE) at a dilution rate of 1 day<sup>-1</sup>. Chemostat continuous cultures were performed in 1.4 L Multifors bioreactors (Infors AG) at a working volume of 750 mL connected to a Hiden HPR-20-QIC mass spectrometer (Hiden Analytical) for online high-resolution off-gas analysis. Steady-state results were collected after OD, gas uptake and production rates had been stable for at least 3–5 working volumes.

### 2.2 Genetic engineering

#### 2.2.1 Genomic and plasmid DNA manipulations

Routine *C. autoethanogenum* genomic DNA extraction for PCR diagnostics was done with PureLink Genomic DNA extraction kit (Invitrogen™, Thermo Fischer Scientific), while plasmid DNA was extracted from *E. coli* using FavorGen FavorPrep™ Plasmid DNA Extraction Mini Kit (Favorgen Biotech Corp). All purified genomic and plasmid DNA fragments were quantified using the NanoDrop™

1000 Spectrophotometer (Thermo Fischer Scientific). PCR for amplification of DNA fragments for sequencing and cloning, routine screening, and analytical procedures was performed using the Phusion™ High-Fidelity DNA Polymerase (Thermo Fischer Scientific). All primers used in this study (see [Supplementary Table S1](#)) were designed using the NetPrimer software (PREMIER Biosoft International) and synthesised by Integrated DNA Technologies. PCR products and DNA fragments were purified from agarose gels with FavorPrep Gel/PCR Purification kit (Favorgen Biotech Corp).

### 2.2.2 Assembly of CRISPR/nCas9 plasmids

A CRISPR/nCas9 gene editing plasmid for *C. autoethanogenum* was constructed based on the pNickClos2.0 plasmid (Addgene plasmid #73228) (Li et al., 2016) with the following modifications to the backbone sequence: origin of transfer and the required traJ coding sequence from pFX01 (Xia et al., 2020) was added to allow potential transfer of the resulting plasmids into recipient cells *via* conjugation. Additionally, one of the two NotI restriction sites was removed to enable convenient cloning of the homology arms (HAs) using NotI and XhoI sites.

To specify the target site for the nCas9 enzyme, single guide RNAs (sgRNAs) were designed using CRISPR RGEN Tools (Park et al., 2015). We used the Basic Local Alignment Search Tool (Altschul et al., 1990) to cross-check that the selected spacer sequences would lead to unique cuts in the genome, thus minimising off-target cleavages. Inverse PCR (iPCR) was employed to clone the unique sgRNA for each target gene into the backbone plasmid to create intermediate plasmids: pGFT021 for LABRINI\_07945 (*hp*) and pGFT022 for LABRINI\_07950 (*nbp*). The two HAs were obtained by PCR amplification of the 1 kb regions upstream and downstream of each target gene from the *C. autoethanogenum* genome using various primer pairs ([Supplementary Table S1](#)). The derived 5' and 3' HA fragments were fused using overlap extension PCR as described by Bryksin and Matsumura (2013) and moved into the appropriate sgRNA-containing vectors using the same technique or *via* restriction cloning. The resulting plasmids containing all necessary parts for CRISPR/nCas9-mediated gene deletion were named pGFT036 for *hp* and pGFT048 for *nbp* KO. See [Supplementary File S1](#) (pGFT036) and [Supplementary File S2](#) (pGFT048) for plasmid maps. Plasmids constructed in this study are listed in [Supplementary Table S2](#).

### 2.2.3 Plasmid transformation into *C. autoethanogenum* using electroporation

Before electroporation, plasmids were propagated and isolated from the *E. coli* NEB Express strain to lose the Dcm methylation pattern, which has been shown to be targeted by the native type IV restriction system of *C. autoethanogenum* (Woods et al., 2019). Preparation of electrocompetent *C. autoethanogenum* cells and transformation using electroporation was performed as previously described (Leang et al., 2013). Electroporated cells were recovered in 10 mL YTF medium for 18–24 h at 37°C with 120 RPM of agitation. Recovery cultures were mixed with 1.5% molten agar YTF supplemented with clarithromycin (4 µg/mL). Transformation plates were incubated inside Oxoid™ AnaeroJars™ (Thermo Fischer Scientific) at 37°C until colonies became visible (in less than 10 days).

### 2.2.4 Transformant colony screening and plasmid curing

Colonies were first inoculated into liquid YTF medium containing clarithromycin and then plated on selective YTF agar to isolate individual transformant colonies. Next, transformant colonies were randomly chosen for colony PCR screening to verify *C. autoethanogenum* (primers *acsB*-F and -R), plasmid presence (primers *oriT*-F and -R), and successful gene deletion. Primers *hp*-F, *hp*-R and, *nbp*-F, *nbp*-R were used to confirm deletions of *hp* and *nbp* genes, respectively. PCR products obtained with the gene deletion control primers were purified and verified by Sanger sequencing.

Plasmid-carrying *C. autoethanogenum* colonies with target gene deletions were then subcultured three or more times in 10 mL YTF medium without the antibiotic before plating on non-selective YTF agar to isolate individual colonies. Next, colonies were randomly chosen and patch-plated on both YTF agar without and with clarithromycin (4 µg/mL). Plasmid loss in colonies that failed to grow in the presence of clarithromycin was confirmed by colony PCR using primers *oriT*-F and *oriT*-R as above. In total, 10 out of 10 colonies for *hp* gene deletion and 1 out of 30 colonies for *nbp* gene deletion had lost their plasmid. The plasmid-cured colonies were then inoculated into liquid YTF medium for outgrowth and preparation of glycerol stocks, stored as  $\Delta hp$  and  $\Delta nbp$ .

## 2.3 Analytical methods

### 2.3.1 Biomass concentration analysis

Biomass concentration (gDCW/L) was estimated by measuring culture OD at 600 nm and using the correlation coefficient of 0.23 between OD and DCW using the methodology established before (Peebo et al., 2014).

### 2.3.2 Extracellular metabolome analysis

Extracellular metabolome analysis from filtered broth samples was performed as described before (Valgepea et al., 2017b). We note that cells produced 2R,3R-butanediol.

### 2.3.3 Bioreactor off-gas analysis

Bioreactor off-gas analysis for the determination of specific gas uptake (CO and H<sub>2</sub>) and production rates (CO<sub>2</sub>, ethanol) (mmol/gDCW/h) have been described before (Valgepea et al., 2017a). The Faraday Cup detector monitored the intensities of H<sub>2</sub>, CO, ethanol, H<sub>2</sub>S, Ar, and CO<sub>2</sub> at 2, 14, 31, 34, 40, and 44 amu, respectively.

### 2.3.4 Carbon balance analysis

Carbon recoveries and balances were determined as described before (Valgepea et al., 2017a). Briefly, carbon balancing of substrate carbon (CO, cysteine) between growth products (acetate, ethanol, 2,3-BDO, CO<sub>2</sub>, biomass) was calculated as C-mol fraction of each product from total C-mol carbon uptake. Carbon recoveries were calculated as the fraction of summed C-mol products from total C-mol substrates. Ethanol stripping and the total soluble CO<sub>2</sub> fraction in culture broth were also considered to achieve more accurate carbon balancing.

## 2.4 Proteome analysis

### 2.4.1 Sample preparation

Proteome analysis was carried out for four biological replicate cultures for each of the three strains: LABrini,  $\Delta hp$ , and  $\Delta nbp$ . *C. autoethanogenum* chemostat cultures were sampled for proteomics by immediately pelleting 2 mL of the culture by centrifugation ( $20,000 \times g$  for 1 min at  $4^\circ\text{C}$ ) and stored at  $-80^\circ\text{C}$  until analysis. Cell pellets were suspended with 10 volumes (relative to pellet volume) of chaotrope-based lysis buffer (6 M guanidine-HCl, 100 mM Tris-HCl pH 8.0, 50 mM dithiothreitol), heated at  $95^\circ\text{C}$  for 10 min and sonicated with the Bioruptor sonicator (Diagenode) for 15 cycles (30 s ON, 60 s OFF; “High” setting) at  $4^\circ\text{C}$ . Next, 0.5 volumes (relative to lysate volume) of Silibeads TypZY-s 0.4–0.6 mm (Sigmund Lindner) beads were added to the lysate and bead beating was carried out with the FastPrep24 device (MP Biomedicals) by  $2 \times 40$  s at 6 m/s. Next, samples were centrifuged at  $17,000 \times g$  for 5 min, and the supernatant was separated from the beads and transferred to a new tube. A small aliquot of the lysate was then precipitated with trichloroacetic acid-deoxycholate (TCA-DOC) precipitation and the protein concentration was determined with the Micro BCA assay (Thermo Fisher Scientific). Next, 20  $\mu\text{g}$  of lysate protein was alkylated with 100 mM chloroacetamide by incubating for 1 h in the dark at room temperature. Samples were then processed, and proteins were digested to peptides by the SP3 protocol as described elsewhere (Hughes et al., 2018).

### 2.4.2 LC-MS/MS analysis

Sample order for LC-MS/MS analysis was randomised to avoid batch effects and blanks were flanked to minimise carry-over. 1  $\mu\text{g}$  of peptides for each sample was injected to an Ultimate 3500 RSLCnano system (Dionex) using a  $0.3 \times 5$  mm trap-column (5  $\mu\text{m}$  C18 particles, Dionex) and an in-house packed (3  $\mu\text{m}$  C18 particles, Dr Maisch) analytical 50 cm  $\times$  75  $\mu\text{m}$  emitter-column (New Objective). Columns were operated at  $45^\circ\text{C}$ . Peptides were eluted at 300 nL/min with an 8%–45% B 90 min gradient (buffer B: 80% acetonitrile + 0.1% formic acid, buffer A: 0.1% formic acid) to a Q Exactive HF (Thermo Fisher Scientific) mass spectrometer (MS) using a nano-electrospray source (spray voltage of 2.5 kV in positive mode). The MS was operated using a data-independent acquisition (DIA) approach (Gillet et al., 2012) with variable isolation windows over a range of 400–1,100 m/z. Briefly, one full range 400–1,100 m/z MS1 scan was collected at a resolution setting of 60,000 (max ion injection time of 60 ms, max of  $3e6$  ions), followed by 25 overlappings (overlap of 1 m/z) DIA isolation windows as follows (start–end m/z, isolation width): 399–472, 25; 471–510, 20; 509–608, 15; 607–703, 20; 702–790, 30; 789–868, 40; 867–966, 50; and 965–1101, 136. Each DIA scan was collected at a resolution setting of 30,000 (max ion injection time of 41 ms, max of  $3e6$  ions), the default charge state was set to +3 and normalised collision energy to 27. The overall method cycle time was approximately 2.3 s.

### 2.4.3 DIA MS data analysis and differential protein expression analysis

DIA MS data was analysed using version 1.8 of the software suite DIA-NN (Demichev et al., 2019) with default settings. The spectral

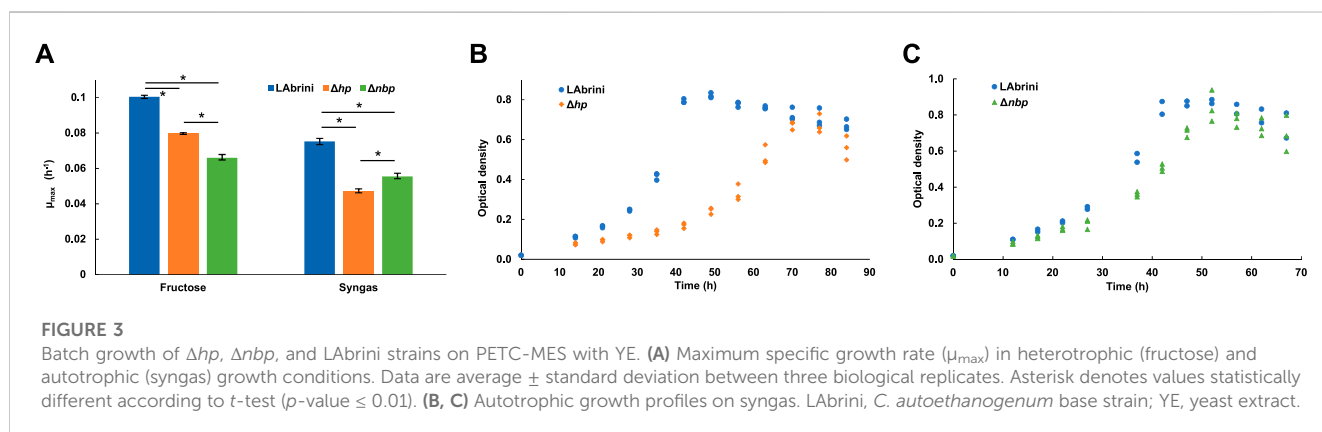

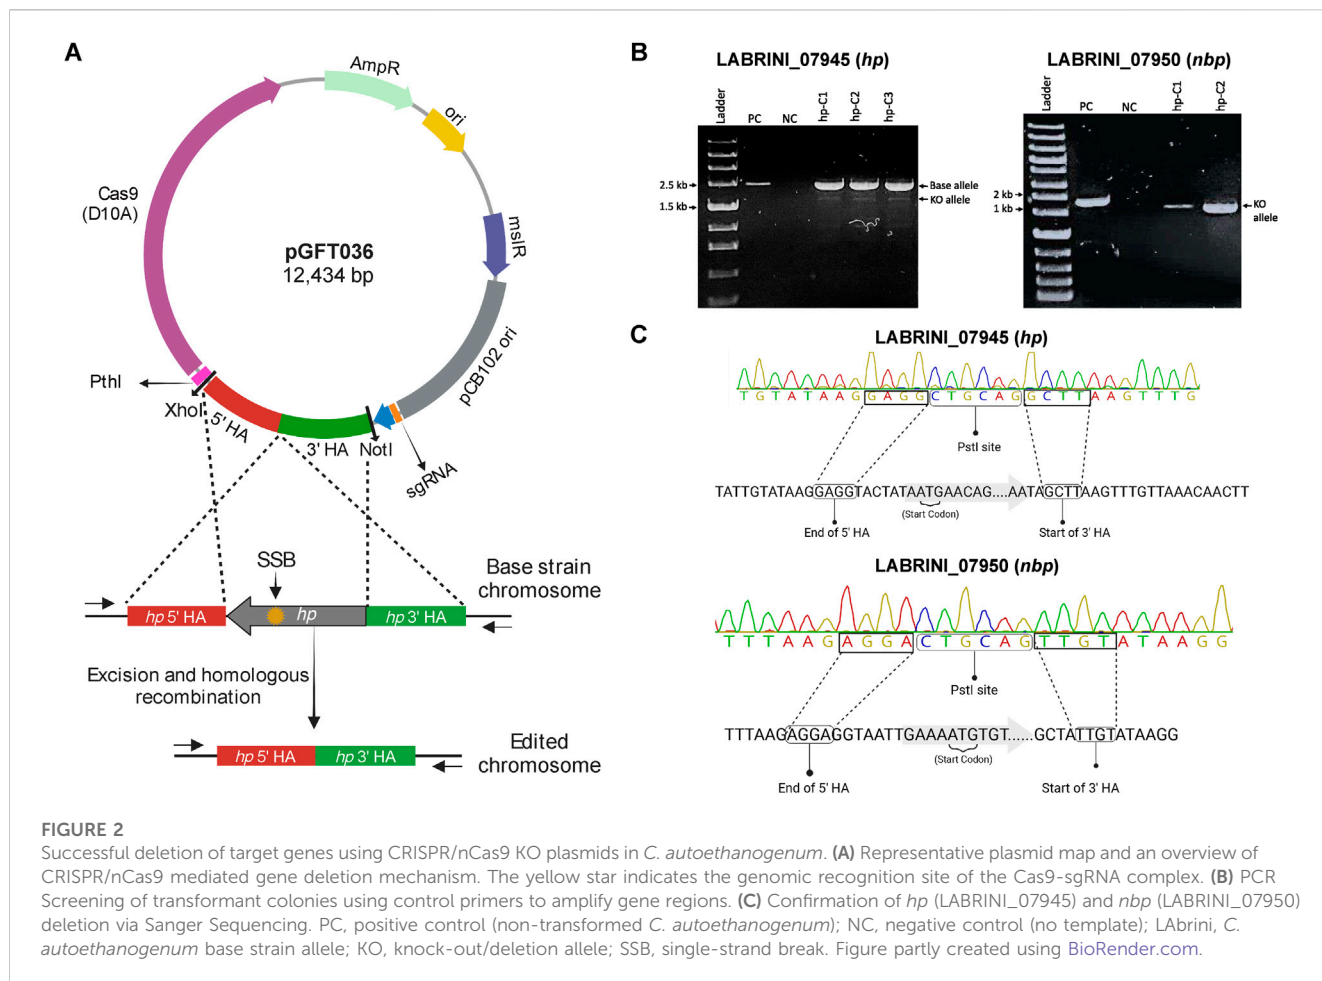

library was generated *in silico* using smart profiling from the protein sequence database of *C. autoethanogenum* LABrini (NCBI Genbank CP110420) (Ingelman et al., 2023) with a precursor of 1% false discovery rate (FDR) filter. The following settings were used for analysis: full trypsin specificity with 1 missed cleavage allowed for peptides with a length of 7–30 AAs; fixed modifications of cysteine carbamidomethylation and methionine N-terminal excision; precursor charge range 1–4 and m/z range 400–1,100; fragment m/z range 200–1,800; double-pass mode for neural network classifier; Robust LC (high precision) for quantification strategy; and RT-dependent cross-run normalization. Label-free protein quantification and normalisation were performed within the DIA-NN workflow using the MaxLFQ method (Cox et al., 2014). We confidently quantitated 28,752 peptides and 2,127 proteins across all samples, and 27,358 peptides and 2,107 proteins on average within each sample after the removal of shared peptides from the analysis.

Protein expression fold-changes (FC) with q-values between  $\Delta hp$  and LABrini, and  $\Delta nbp$  and LABrini were determined using the software Perseus (Tyanova et al., 2016) with Student's T-test. Only proteins with at least two peptides in all 12 samples (1,835) analysed were used to ensure higher quantification accuracy. Proteins were considered to be differentially expressed by an FC > 1.5 and a q-value < 0.05 after FDR correction (Benjamini and Hochberg, 1995). Differentially expressed proteins are presented in Supplementary Table S3. Proteomics data have been deposited to the ProteomeXchange Consortium (<http://proteomecentral.proteomexchange.org>) via the PRIDE partner repository (Perez-Riverol et al., 2022) with the data set identifier PXD040151.

## 3 Results and discussion

### 3.1 Single-gene deletion of *hp* and *nbp* in *C. autoethanogenum* using CRISPR/nCas9 knock-out plasmids

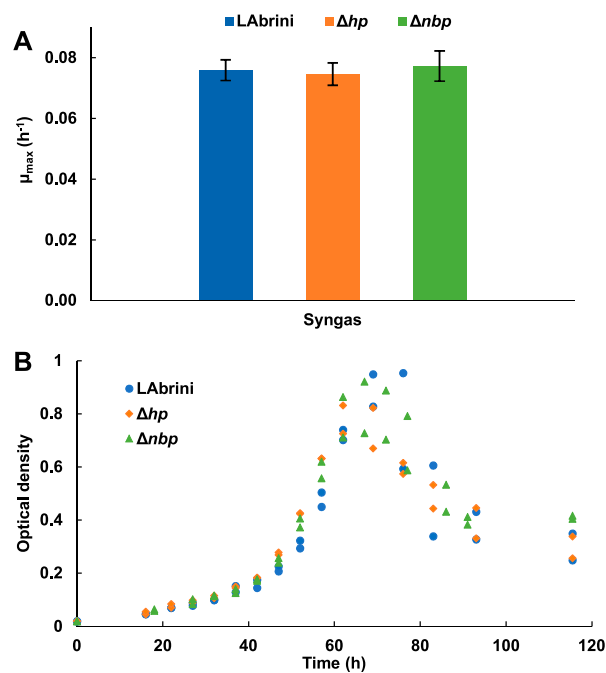

To study the role of two genes adjacent to the  $C_1$ -fixing gene cluster (Figure 1) with unclear functions, LABRINI\_07945 (*hp*) and LABRINI\_07950 (*nbp*), each gene was targeted for deletion using CRISPR/nCas9. Plasmids pGFT036 and pGFT048 carrying required components (Figure 2A) for *hp* and *nbp* deletion, respectively, were transferred into *C. autoethanogenum* by electroporation that yields transformation efficiencies up to 200 CFU/ $\mu\text{g}$  DNA in our laboratory. We obtained 40 and 2 colonies for *hp* and *nbp* deletion, respectively, and colony PCR screening of 6 colonies for *hp* and 2 for *nbp* deletion confirmed *C. autoethanogenum* genotype and the presence of our relatively large plasmid (~12.5 kb) in all colonies. The gene deletion control PCR showed that all the *hp* colonies screened had a mixed base strain/knock-out (KO) genotype evidenced by the presence of both the 2444-bp fragment of the base strain allele and the predicted 2103-bp fragment of the KO allele (Figure 2B). Six rounds of liquid selective sub-culturing of the mixed colonies was needed to obtain 1 colony (from 20 screened) with a clean *hp* KO genotype (Figure 2C). In contrast, the 2 *nbp* colonies (*nbp*-C<sub>1</sub> and *nbp*-C<sub>2</sub>) obtained showed a 1444-bp fragment of the desired KO allele, i.e., a clean KO genotype (Figure 2B). Sanger

sequencing confirmed both *hp* and *nbp* gene deletions in selected colonies and the presence of a PstI site, proving that the provided plasmid-based DNA repair template, in the form of the fused 1 kb HA interspaced with the PstI site, was used during homologous recombination to repair the nick from nCas9 (Figure 2C). Successful deletion of both genes was also confirmed by proteome analysis (see below). Finally, the obtained  $\Delta hp$  and  $\Delta nbp$  cells were cured of the plasmid before proceeding with phenotypic characterisation.

### 3.2 Deletion of *hp* and *nbp* genes confer growth defects in rich-medium batch cultures

Next, we grew  $\Delta hp$  and  $\Delta nbp$  strains in batch cultures on PETC-MES medium with YE (i.e., rich medium) in heterotrophic (fructose) and autotrophic (syngas: CO+H<sub>2</sub>+CO<sub>2</sub>) conditions to investigate potential phenotypic effects of *hp* and *nbp* deletions. Interestingly, the maximum specific growth rate ( $\mu_{max}$ ) of both mutant strains was significantly

**FIGURE 4**

Autotrophic batch growth of  $\Delta hp$ ,  $\Delta nbp$ , and LABrini strains in PETC-MES without YE. (A) Maximum specific growth rates ( $\mu_{max}$ ) on syngas. Data are average  $\pm$  standard deviation between two biological replicates. (B) Growth profiles on syngas. LABrini, *C. autoethanogenum* base strain; YE, yeast extract.

impaired compared to the *C. autoethanogenum* base strain “LABrini” on both fructose and syngas (Figure 3A). The  $\mu_{max}$  for the  $\Delta hp$  strain was  $0.08 \pm 0.001$  (average  $\pm$  standard deviation) and  $0.05 \pm 0.001$  on fructose and syngas, respectively, while for the  $\Delta nbp$  strain, the  $\mu_{max}$  was  $0.07 \pm 0.002$  on fructose and  $0.06 \pm 0.001$  on syngas (Figure 3A). The LABrini base strain showed  $\mu_{max}$  values of  $0.10 \pm 0.001$  on fructose and  $0.08 \pm 0.001$  on syngas. Thus,  $\mu_{max}$  for deletion strains were substantially lower compared to base strain: for  $\Delta hp$ , 21% and 37% lower on fructose and syngas and for  $\Delta nbp$ , 34% and 26% lower on fructose and syngas, respectively (Figure 3A). Interestingly,  $\Delta hp$  had a more pronounced growth defect on syngas, while  $\Delta nbp$  was affected more on fructose. The  $\mu_{max}$  values for both growth conditions were also statistically different between deletion strains. In addition to the lower  $\mu_{max}$ ,  $\Delta hp$  strain exhibited a longer lag phase and slightly lower peak OD on syngas compared to the base strain LABrini (Figure 3B). The growth profile and peak OD of the  $\Delta nbp$  strain, however, were similar to LABrini despite the lower  $\mu_{max}$  values (Figure 3C). Altogether, our results demonstrate that the deletion of either the *hp* or the *nbp* gene confers significant growth defects for hetero- and autotrophic rich medium batch cultures, suggesting a notable role for both genes in the physiology of *C. autoethanogenum*.

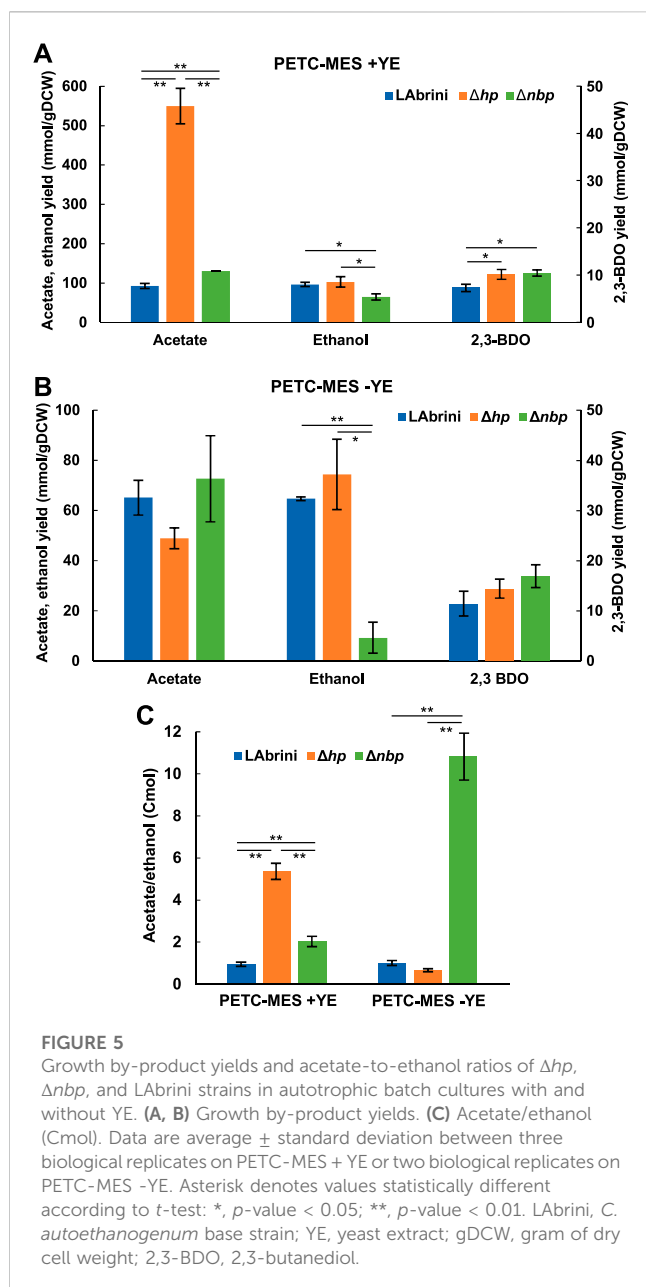

### 3.3 Deletion of *hp* and *nbp* show no effects on growth in minimal medium autotrophic batch cultures

We also investigated the growth of all three strains in PETC-MES medium without YE to assess the effects of *hp* and *nbp*

deletions on autotrophic growth on syngas in minimal medium batch cultures. Intriguingly, there was no difference in the  $\mu_{max}$  values between the three strains:  $0.08 \pm 0.004$ ,  $0.08 \pm 0.005$ , and  $0.08 \pm 0.003$  for the  $\Delta hp$ ,  $\Delta nbp$ , and LABrini strains, respectively (Figure 4). Although one would expect slower growth in minimal medium,  $\Delta hp$  and  $\Delta nbp$  strains grew faster in minimal medium compared to rich medium, whereas LABrini showed similarly high  $\mu_{max}$  values for autotrophic growth of acetogens on both media. Like the  $\mu_{max}$  data, the three strains did not show significant variations in peak OD and growth curves (i.e., lag phase and entry into stationary phase) (Figure 4B). Thus, both genes seem to play a role in *C. autoethanogenum* for utilisation of complex nutrients due to significant growth defects in rich medium with no phenotypic effects in minimal medium for  $\Delta hp$  and  $\Delta nbp$  strains.

### 3.4 Deletion of *hp* and *nbp* alter growth by-product yields in autotrophic batch cultures

We determined the production yields (mmol/gDCW) of *C. autoethanogenum* growth by-products — ethanol, acetate, and 2,3-butanediol (2,3-BDO) — during the above-described autotrophic batch cultures to check if these are affected by the deletion of either the *hp* or the *nbp* gene. Remarkably, the  $\Delta hp$  strain showed a >5-fold higher acetate yield ( $550 \pm 45$  mmol/gDCW) relative to LABrini ( $92 \pm 7$  mmol/gDCW) during growth in rich medium (Figure 5A). The production of 2,3-BDO was also slightly higher for  $\Delta hp$  compared to LABrini ( $10 \pm 1$  vs.  $7 \pm 1$  mmol/gDCW).

While the ethanol yield was not different for  $\Delta hp$  when compared to LAbri (96  $\pm$  5 vs. 102  $\pm$  13 mmol/gDCW), ethanol production did not coincide with acetate production in the  $\Delta hp$  strain (data not shown). Namely,  $\Delta hp$  was producing acetate in the early exponential growth phase and started producing ethanol only in the late exponential phase.

Also, the  $\Delta nbp$  strain showed significantly different product yields compared to LAbri during growth in rich medium: 41% higher acetate (130  $\pm$  0.2 vs. 92  $\pm$  7 mmol/gDCW), 44% higher 2,3-BDO (10  $\pm$  1 vs. 7  $\pm$  1 mmol/gDCW), and 33% lower ethanol compared to LAbri (65  $\pm$  8 vs. 96  $\pm$  6 to mmol/gDCW) (Figure 5A). In addition, both acetate and ethanol production yields were different between the two deletion strains. The substantially higher acetate production yield of the  $\Delta hp$  strain might indicate that deletion of the *hp* gene improves the uptake

of YE components and their catabolism to acetate. However, this did not lead to faster growth, thus, acetate production was potentially not linked to ATP production.

We observed no difference in the product yields between the  $\Delta hp$  strain and LAbri on minimal medium (Figure 5B), which is not surprising as growth was also comparable (Figure 4). However, despite similar growth for  $\Delta nbp$  and LAbri strains on minimal medium (Figure 4), the  $\Delta nbp$  strain showed an 86% lower ethanol yield than LAbri (9  $\pm$  6 vs. 65  $\pm$  1 to mmol/gDCW) while acetate and 2,3-BDO yields were similar (Figure 5B). Only the ethanol production yield was different between the deletion strains on minimal medium. Interestingly, while LAbri maintained the acetate-to-ethanol ratio at  $\sim$ 1 on both media, the ratio was higher for the  $\Delta hp$  strain ( $\sim$ 5 vs.  $\sim$ 1) and lower for the  $\Delta nbp$  strain ( $\sim$ 2 vs.  $\sim$ 11) on rich medium compared to minimal medium during autotrophic growth (Figure 5C). These ratios are in the range of those previously seen in autotrophic batch and continuous bioreactor cultures of *C. autoethanogenum* (Valgepea et al., 2017a; Valgepea et al., 2018; Ingelman et al., 2023). Our results imply that both *hp* and *nbp* genes play a notable role in carbon distribution between the two major by-products — acetate and ethanol — during autotrophic batch growth of *C. autoethanogenum*.

### 3.5 Deletion of *nbp* does not affect autotrophic growth in nickel-supplemented minimal medium batch cultures

Since Nbp is annotated as a nickel binding protein and deletion of *nbp* strongly affected growth in rich medium cultures (Figures 3, 5), we hypothesised that the effects could arise from a potentially lower capacity of the  $\Delta nbp$  strain to catabolise the higher nickel levels in rich medium, i.e., YE contains nickel. We thus tested the effect of nickel supplementation on autotrophic batch growth of  $\Delta nbp$  and LAbri strains in PETC-MES without YE. We added 0.6 mg/L NiCl<sub>2</sub>·6H<sub>2</sub>O to the 0.2 mg/L in PETC-MES (0.8 mg/L final concentration) to facilitate potential effects on growth as a previous study showed variable influence of nickel in the range of 0.1–0.4 mg/L (NiCl<sub>2</sub>·6H<sub>2</sub>O) on heterotrophic growth of *C. ljungdahlii* (Mann et al., 2022).

We observed no difference between  $\mu_{max}$  values of  $\Delta nbp$  and LAbri strains growing on syngas and in PETC-MES medium without YE with supplemented nickel (Figure 6A). These values were not statistically significantly (*p*-value > 0.05) different from respective values during growth without additional nickel (Figure 4A). Likewise, by-product yields between the two strains with nickel supplementation did not differ (Figure 6B). Both acetate and ethanol production yields with nickel addition did, however, differ from yields observed during growth without extra nickel (Figure 5B). Effect of nickel levels on acetate and ethanol production is also seen during heterotrophic growth of *C. ljungdahlii* (Mann et al., 2022). Our results showed that deletion of *nbp* did not affect autotrophic growth in nickel-supplemented minimal medium batch cultures. As several enzymes in the WLP are dependent on nickel, the potential role of *nbp* in *C. autoethanogenum* nickel metabolism remains to be further elucidated.

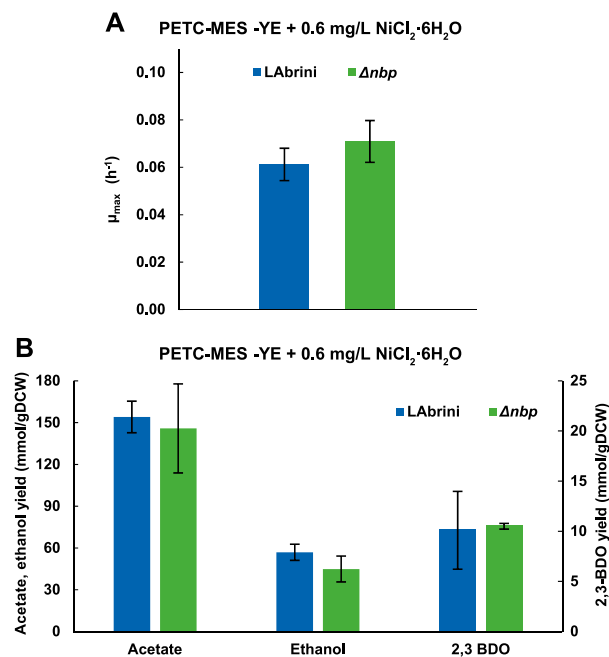

FIGURE 6

Effect of nickel supplementation on autotrophic (syngas) batch growth and growth by-product yields of  $\Delta nbp$  and LAbriini strains in PETC-MES without YE. (A) Maximum specific growth rates ( $\mu_{max}$ ). (B) Growth by-product yields. Data are average  $\pm$  standard deviation between three biological replicates. LAbriini, *C. autoethanogenum* base strain; YE, yeast extract; gDCW, gram of dry cell weight; 2,3-BDO, 2,3-butanediol.

### 3.6 Deletion of *hp* and *nbp* affect growth characteristics of steady-state chemostat cultures

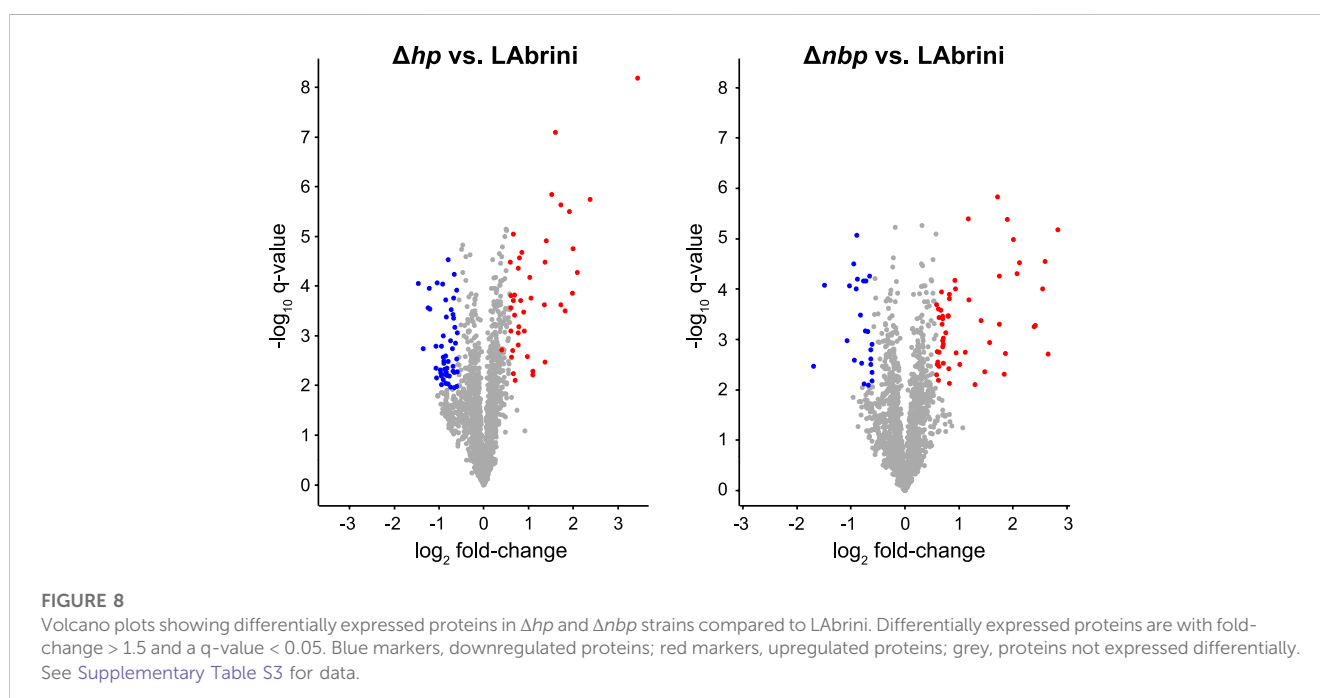

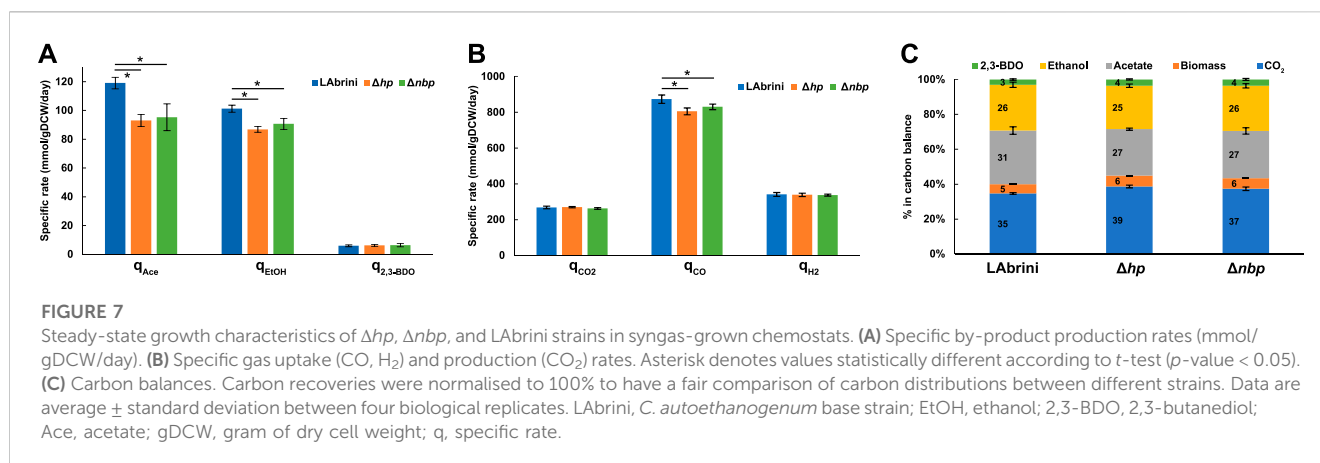

We also compared the performance of the mutant strains to the LAbriini base strain in steady-state bioreactor continuous cultures as these yield high-quality physiological data (Adamberg et al., 2015; Valgepea et al., 2018) and are also the industrially relevant fermentation mode for acetogens (Köpke and Simpson, 2020). Cells were grown in minimal medium in syngas chemostats at a dilution rate of 1 day<sup>-1</sup> and steady-state data at biomass concentrations  $\sim$ 1.5 gDCW/L were collected for by-product production (ethanol, acetate, 2,3-BDO) and gas uptake and production (CO, H<sub>2</sub>, CO<sub>2</sub>) analysis.

While acetate production in minimal medium batch cultures was similar across all three strains, both  $\Delta hp$  and  $\Delta nbp$  strains showed lower specific acetate production rates ( $q_{ace}$ ; mmol/gDCW/day) in chemostats (Figure 7A). Specific ethanol production rates ( $q_{EtOH}$ ) were also lower for both deletion strains compared to LAbriini (Figure 7A), whereas ethanol production differed only for the  $\Delta nbp$  strain in batch cultures (Figure 5). Production of 2,3-BDO ( $q_{2,3-BDO}$ ) was similar across the three strains in chemostats (Figure 7A). These steady-state data are consistent with above-described batch data by showing that both *hp* and *nbp* genes affect carbon distribution during autotrophic growth of the model-acetogen *C. autoethanogenum*. Still, differences in bioreactor chemostat and bottle batch data demonstrate the importance of testing strains in the industrially relevant fermentation mode for acetogens (Köpke and Simpson, 2020).

Bioreactor off-gas analysis revealed that the specific CO uptake rates ( $q_{CO}$ ; mmol/gDCW/day) were slightly lower for both deletion strains compared to LAbriini ( $873 \pm 19$ ); by 8% for the  $\Delta hp$  strain ( $805 \pm 19$ ) and by 5% for the  $\Delta nbp$  strain ( $830 \pm 15$ ) (Figure 7B). At the same time, we detected no differences in the specific H<sub>2</sub> uptake rates ( $q_{H_2}$ ; mmol/gDCW/day) and CO<sub>2</sub> production rates ( $q_{CO_2}$ ; mmol/gDCW/day) among the three strains (Figure 7B). The slightly higher  $q_{CO_2}/q_{CO}$  and  $q_{H_2}/q_{CO}$  for both deletion strains indicates that cells needed to increase the generation of reducing power in the form of reduced ferredoxin as a response to gene deletion since both CO and H<sub>2</sub> oxidation supply reduced ferredoxin (Bertsch and Müller, 2015; Pavan et al., 2022). Quantification of carbon flows from substrates to products showed that both  $\Delta hp$  and  $\Delta nbp$  strains diverted more carbon to biomass and CO<sub>2</sub> with a concomitant lower carbon flux to ethanol and acetate (Figure 7C). The slightly lower acetate-to-ethanol ratios for  $\Delta hp$  (1.2) and  $\Delta nbp$  (1.1) compared to LAbriini (1.3) are consistent with higher  $q_{CO_2}/q_{CO}$  for deletion strains since ethanol production generally results in a greater loss of carbon from CO as CO<sub>2</sub> (Bertsch and Müller, 2015).

### 3.7 Proteome analysis reveals intriguing effects of deletion of *hp* and *nbp* genes

We used proteomics to determine the effects of *hp* and *nbp* gene deletions on protein expression in the above-described chemostat cultures of *C. autoethanogenum*. Our analysis quantified 93 differentially expressed proteins (fold-change > 1.5 and a *q*-value < 0.05) between  $\Delta hp$  and LAbriini, and 77 between  $\Delta nbp$

and LAbri (Figure 8; Supplementary Table S3). Proteomics also confirmed the deletion of each gene in respective strains as no peptides for either protein in corresponding strains were detected. Additionally, the data showed no effect of deletion of either gene on expression of the protein encoded by the other gene, i.e., *hp* deletion on Nbp expression or *nbp* deletion on Hp expression. Intriguingly, deletion of either gene increased the expression of the methyltransferase (AcsE; 07970) and a component of the correnoid iron sulphur protein (AcsD; 07980) (Table 1) that are linked to a critical activity of the WLP: synthesis of acetyl-CoA. AcsE and AcsD supply the methyl group to the carbon monoxide dehydrogenase (AcsA; 08025) and acetyl-CoA synthase (AcsB; 07965) CODH/ACS enzyme complex (Lemaire and Wagner, 2021), that is essential for autotrophic growth of *C. autoethanogenum* (Liew et al., 2016). At the same time, the expression of AcsB was repressed in both deletion strains

(Table 1). These are all among the top 10 most abundant proteins for autotrophic growth of *C. autoethanogenum*, except AcsA (Valgepea et al., 2022). These results show that the two genes adjacent to the  $\text{C}_1$ -fixing cluster studied here—*hp* and *nbp*—affect the expression of key proteins for  $\text{C}_1$ -fixation. Notably, the effect of *hp* and *nbp* on  $\text{C}_1$ -fixation extends beyond the WLP as the expression of the most abundant CODH in *C. autoethanogenum* (Valgepea et al., 2022)—CooS1; 15015—was repressed in both mutant strains (Table 1). Further work is needed to understand the interplay between the *hp*, *nbp*, and the affected enzymes with a central role in the autotrophic growth of *C. autoethanogenum*.

Deletion of our target genes also affected the expression of proteins involved in the synthesis of the most attractive native product of *C. autoethanogenum*: ethanol. In contrast to the lowered ethanol production in the deletion strains, proteome analysis revealed that

TABLE 1 Key protein expression changes in  $\Delta hp$  and  $\Delta nbp$  strains compared to LABrini.

Protein ID	Description of protein product	$\Delta hp$ vs. LABrini			$\Delta nbp$ vs. LABrini		
		Log <sub>2</sub> FC	FC	q-value	Log <sub>2</sub> FC	FC	q-value
<i>C<sub>1</sub>-fixation</i>

LABRINI_00445	Aldehyde ferredoxin oxidoreductase	0.61	1.5	0.02	0.02	1.6	0.02
LABRINI_18700	Bifunctional AdhE1	0.77	1.7	0.01	2.07	4.2	< 0.01

ID, identifier; FC, fold-change. Positive FC means upregulation, negative downregulation. See [Supplementary Table S3](#) for all differentially expressed proteins.

expression of alcohol dehydrogenases (19700 and 18005) was elevated in both mutant strains, including the most abundant alcohol dehydrogenase in *C. autoethanogenum* (Valgepea et al., 2022); Adh4, 09125 (Table 1). Similarly, increased expression of both aldehyde ferredoxin oxidoreductases (AOR1, 00445 and AOR2, 00495), that couple ethanol synthesis to ATP production and the bifunctional acetaldehyde-CoA/alcohol dehydrogenase AdhE1 (18700) were measured in deletion strains. Such seeming discrepancies between either the transcripts or proteins linked to ethanol synthesis and the measured ethanol production have been detected in *C. autoethanogenum* before (Valgepea et al., 2017a; Valgepea et al., 2018). Thus, more systemic and in-depth investigations are required to decipher the genotype-phenotype relationships for ethanol synthesis in acetogens.

Among other differentially expressed proteins, it was unexpected to see repression of 13 ribosomal proteins in the  $\Delta hp$  strain (1.7- to 2.3-fold,  $q < 0.05$ ; [Supplementary Table S3](#)). In addition, several oxidoreductases (05235, 14800, and 18000; ~2-fold,  $q < 0.03$ ) and sigma-54-related transcriptional regulators (14025 and 00450; ~3.2- and 1.6-fold,  $q < 0.05$ ) were upregulated in the deletion strains. Also noteworthy is the ~1.8-fold ( $q < 0.01$ ) upregulation of a PocR ligand-binding domain-containing protein (16380) in both  $\Delta hp$  and  $\Delta nbp$  strains, as we recently identified a missense mutation in the PocR gene of a CO-evolved *C. autoethanogenum* strain obtained via adaptive laboratory evolution (Ingelman et al., 2023). Moreover, PocR has an alternative annotation in *C. autoethanogenum* as a histidine kinase (Humphreys et al., 2015) that regulates sporulation and metabolism in Clostridia (Xin et al., 2020).

## 4 Conclusion

In summary, our study shows that CRISPR/nCas9 can effectively be used for targeted gene deletion in the

industrially relevant acetogen *C. autoethanogenum* and provides valuable insights to accelerate the rational genetic engineering of acetogen cell factories. Additionally, the characterisation of the constructed deletion strains offers valuable clues to the *in vivo* functionalities of the *hp* and *nbp* genes that seem to influence both growth and product patterns of *C. autoethanogenum* during autotrophic growth. Furthermore, our proteomics results shed light on enzymes that potentially play a key role in ethanol production. Future work will need to confirm the biochemical function of closely linked genes in the WLP and identify possible targets for improving carbon fixation efficiencies.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/[Supplementary Material](#).

## Author contributions

Conceptualization: UJN, KR, and KV; Methodology: UJN, KR, KS, AH, MK, and KV; Formal analysis: UJN, KR, LD, PP, and KV; Investigation: UJN, KR, LD, PP, and KV; Resources: KV; Writing—Original Draft: UJN, KR, and KV; Writing—Review and Editing: UJN, KR, LD, PP, KS, AH, MK, and KV; Supervision: KV; Project Administration: KV; Funding Acquisition: KV. All authors listed have made a substantial, direct, and intellectual contribution to the work and approved it for publication.

## Funding

This work was funded by the European Union's Horizon 2020 research and innovation programme under grant agreement N810755 and the Estonian Research Council's grant agreement PSG289.

## Acknowledgments

We thank Bastian Molitor and Peng-Fei Xia for providing us the pFX01 plasmid.

## Conflict of interest

LanzaTech has interest in commercial gas fermentation with *C. autoethanogenum*. AH and MK are employees of LanzaTech.
