The Sediment Selectivity of *Perinereis*  
*aibuhitensis* Larvae: Active or  
Passive? *Front. Mar. Sci.* 8:697736.  
doi: 10.3389/fmars.2021.697736

The selectivity of *Perinereis aibuhitensis* larvae on different sediment types was studied using an experimental behavioral device in the lab. There were six types of sediment with different organic matter content: 2.19, 2.30, 2.86, 3.25, 3.51, and 5.52%. The results indicated significant differences in the six treatments' organic matter content ( $p < 0.05$ ). When the *P. aibuhitensis* larvae initially attached to the sediment, the larvae's density showed no significant difference among the six treatments. The density of larvae decreased gradually during the experimental period. It increased with the increasing organic matter content in sediment at every sampling time, but there was no significant difference ( $p > 0.05$ ). The larvae's specific growth rate in the first month was significantly higher than those in the second and third months ( $p < 0.05$ ). The mortality showed no significance at different sediments in equal sampling times, but the mortality was lower in high organic matter content sediments. This study showed that the *P. aibuhitensis* larvae did not make an active selection; random selection happened when initially attached to the sediment with different organic matter contents. Higher organic matter content in the sediment was more conducive to larvae survival, and the organic matter content is the limitation factor on the mortality and the density. The different densities in the natural habitat of *P. aibuhitensis* might occur due to the passive selection by the environment.

## INTRODUCTION

Polychaeta, one of the most typical taxon of benthic communities, is a common infauna of the coastal intertidal zone involved in the reworking of sediment and ecological recovery in natural waters (Heilskov and Holmer, 2001; Koo and Seo, 2017; Chouikh et al., 2020; Gopal et al., 2020). The bioturbation behaviors of polychaetes within the sediment include feeding, burrowing, and moving, which promote nutrients exchange and oxygen flux at the sediment-water surface resulting in accelerated mineralization and decomposition of the sediment's organic matter (Duport et al., 2006, 2007). The density and biomass of polychaetes influence environmental recovery efficiency induced by bioturbation (Duport et al., 2006; Hu et al., 2020).

Polychaetes biomass distribution differs by habitat location and tidal zones. According to the studies of Hylleberg (1975), Kihlslinger and Woodin (2000), and Fang et al. (2018), polychaetes

prefer sediment with higher organic content. This tendency probably gives rise to the difference in biomass distribution. However, Meng et al. (2020) found that *Perinereis aibuhitensis* exhibited a slight (not significant) selectivity for different natural sediment types, probably due to their hydrogen sulfide content. Compared with adult polychaetes, larvae are more sensitive to environmental changes. A specific sediment preference possibly caused the distributions of adult polychaetes during the larval stage. Shi and Zhao (1993) found that sediment quality influences the growth and survival rate of *P. aibuhitensis* larvae. A mixture consisting of mud and sand was more conducive to the larvae's growth and survival. In the polychaetes natural habitat, how the different distributions happened in a similar environment? Thus, to elucidate sediment selectivity of polychaete larvae is required. Here whether the larvae preferred sediment when they are attached (initiative) or if they could be selected by the environmental conditions after attachment (passive) is examined.

*P. aibuhitensis* (Grube, 1878), a common polychaete in intertidal and estuarine zones (Sun and Yang, 2004), has a high tolerance to polluted environments (Li et al., 2017) and a significant impact on bioturbation (Koo and Seo, 2017). In a previous study, we found that environmental parameters, such as organic matter and hydrogen sulfide at different tidal zones of the natural habitat of *P. aibuhitensis* were significantly different (Fang et al., 2017). The biomass distribution was also different among tidal zones. Here, the distribution of *P. aibuhitensis* larvae based on the substrate's organic matter composition was evaluated after attachment to the sediment. Moreover, the survival and growth rates of the larvae in different substrates were determined. The work presented here will provide helpful information on the impacts of sediment's organic matter content on the attachment and survival of *P. aibuhitensis* larvae, which could explain polychaetes distribution in sediments.

## MATERIALS AND METHODS

### Hatching *P. aibuhitensis* Larvae

A 100 L sterilized vat with filtered seawater was prepared for insemination. The water temperature was adjusted to  $20 \pm 1^\circ\text{C}$ . Slight and continuous aeration was provided. The parental *P. aibuhitensis* obtained from a polychaete farm in Rushan, Weihai (female  $3.7 \pm 0.2$  g; male  $3.5 \pm 0.2$  g) were put into the vat naturally spawn. Four hours after spawning and the parents were removed.

The larvae's development was observed once a day under an anatomical lens (Olympus, SZ51-SET). After 7–10 days, when the nectochaeta larvae with four chaetigerous segments accounted for more than 80% of the total larvae, the water was stirred evenly and divided into three experimental devices (Figure 1) to a final density of 1.5 ind./mL. During this stage, there was no other food provided.

### Preparation of Sediments

The sediments used in the experiment were collected from the intertidal zone of the natural habitat of *P. aibuhitensis*. Sediments were air-dried and crushed for use. Kelp powder and

commercial shrimp feed were mixed at a 9:1 weight ratio. The mixed powder was added to the crushed sediments to make experimental sediments according to the weight proportion of 0, 1, 2, 4, 6, and 12%, which are numbered as 1#, 2#, 3#, 4#, 5#, and 6#. The experimental sediments were placed in individual experimental devices in the order of proportions and soaked in seawater with continuous aeration to make them naturally settle. Sediments were allowed to stabilize for 3 weeks, with daily seawater replacement. The sediment depth after sedimentation was about 20 cm.

## Experimental Management and Data Measurement

At the four chaetigerous segments stage, nectochaeta larvae were laced into the experimental device and fed with the appropriate amount of *Chlorella* spp (1,000–2,000 cell/ml). The density of larvae in the water was monitored daily, and the initial number of *P. aibuhitensis* in the sediment was determined when there were no planktonic larvae in the water. Before density determination, the seawater in the device was slowly siphoned out without disturbing the sediment, and then two  $2\text{ cm} \times 5\text{ cm}$  and two  $3\text{ cm} \times 5\text{ cm}$  hard plastic plates were inserted into the sediment to form a cuboid with  $2\text{ cm} \times 3\text{ cm} \times 5\text{ cm}$  in width, length, and height. A total of three samples were monitored monthly. All the sediment in the cuboid was removed and placed into a 200 mL glass beaker. The seawater was added into the beaker and gently mixed the seawater and sediment to be muddy water. The end of the plastic eyedropper was cut off to draw the sediment from the beaker slowly. The muddy water was then placed in a petri dish and gently shaken so that it would be evenly spread over the petri dish. The point is that the spread muddy water must be semitransparent. The larvae in the petri dish were observed under an anatomical lens, and the number and size of the larvae were determined. The size was assessed by the number of segments in the larvae. The procedure was repeated until all the sediment in the beaker was observed. The observation was performed monthly. To ensure the *P. aibuhitensis* density measures' accuracy, the partitions were used to separate the vacant part from other sediments after taking the sediment samples.

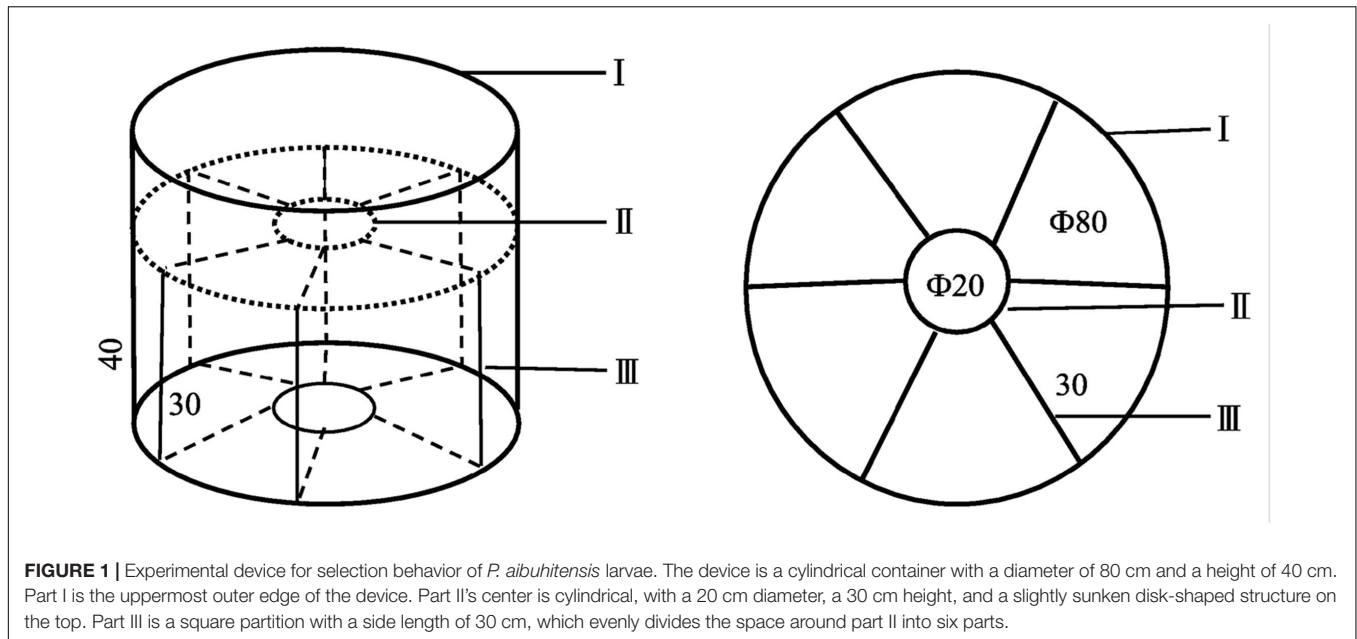

### Determination of Organic Matter

Sediment samples from different depths (surface layer: 0–0.5 cm; deep layer: about 5 cm) were dried in an oven (DHG-9240A, Shanghai) at  $70^\circ\text{C}$  for 72 h to a constant weight. The dried samples were ground with a grinder. About 1.0 g of the sediment was placed in a crucible and calcined in a muffle furnace (SX3-4-10X, Yantai) at  $450^\circ\text{C}$  for 6 h to determine the content of organic matter in the sediment.

### Larvae Density and Mortality

The density of larvae in the sediment was determined every month. The number of larvae per unit area was recorded as density.

$$D = \frac{n}{S}$$

**FIGURE 1** | Experimental device for selection behavior of *P. aibuhitensis* larvae. The device is a cylindrical container with a diameter of 80 cm and a height of 40 cm. Part I is the uppermost outer edge of the device. Part II's center is cylindrical, with a 20 cm diameter, a 30 cm height, and a slightly sunken disk-shaped structure on the top. Part III is a square partition with a side length of 30 cm, which evenly divides the space around part II into six parts.

Where  $D$  (ind/cm<sup>2</sup>) is the larvae density,  $n$  (ind) is the number of larvae, and  $S$  (cm<sup>2</sup>) is the sampling area.

The mortality was calculated using the ratio of the density measured at the sampling time to the density measured at the previous sampling time.

$$M = \left( 1 - \left( \frac{D_n}{D_{n-1}} \right) \right) \times 100\%$$

Where  $M$  (%) is the mortality,  $D_n$  (ind/cm<sup>2</sup>) is the density of the  $n^{\text{th}}$  month, and  $D_{n-1}$  (ind/cm<sup>2</sup>) is the density of the  $(n-1)^{\text{th}}$  month.

### Specific Growth Rate

The specific growth rate (SGR) of the larvae was measured monthly. The SGR was calculated based on the number of larva segments recorded at each sampling.

$$\bar{S} = \frac{s_1 + s_2 + s_3 + \dots + s_m}{m}$$

Where  $\bar{S}$  is the average number of segments,  $m$  is the number of *P. aibuhitensis* larvae, and  $s$  is the number of segments in *P. aibuhitensis*.

$$SGR = \frac{\ln \left( \frac{\bar{S}_n}{\bar{S}_{n-1}} \right)}{T} \times 100\%$$

Where  $\bar{S}_n$  and  $\bar{S}_{(n-1)}$  are the average number of segments measured at the  $n^{\text{th}}$  and  $(n-1)^{\text{th}}$  month, respectively, and the  $T$  (d) is the sampling interval in days.

### Data Processing

The data were analyzed by SPSS 23.0 statistical analysis software, and one-way analysis of variance (ANOVA) was used

to compare the organic matter content in sediments. Two-way ANOVA was used to compare the effects of sediment type and sampling time on the specific growth rate, density, and larvae mortality. Significant ANOVAs were followed by a LSD's multiple comparison. Differences were statistically significant if  $p < 0.05$ .

## RESULTS

### Organic Matter Content in Sediment

The organic matter content between surface and deep layers of the sediment in all types of sediment was significantly different ( $p < 0.05$ , **Figure 2**). Moreover, the organic matter content in the sediments increased in turn from 1# to 6#, which was in line with the experimental design's expectation. The average organic matter content of sediment from 1# to 6# were 2.19, 2.30, 2.86, 3.25, 3.51, and 5.52%, respectively.

### Specific Growth Rate

Two-way ANOVA showed that the sampling time, the sediment type, and the interaction of the two factors have a significant impact on the specific growth rate (SGR) of the polychaete (time:  $F = 14043$ ,  $p < 0.05$ ; type of sediment:  $F = 6.045$ ,  $p < 0.05$ ; Interaction:  $F = 67.277$ ,  $p < 0.05$ ). There were significant differences in the three months' SGR under the same sediment ( $p < 0.05$ , **Figure 3**). The first month's SGR was significantly higher than that in the second and third months ( $p < 0.05$ ). There was no significant difference in the same month's SGR among different sediments ( $p > 0.05$ ).

### Density

The results of two-way ANOVA showed that the sampling time had a significant effect on the density of larvae in different

sediments ( $F = 15.19, p < 0.05$ ), and the sediment had a significant effect on the density of larvae ( $F = 2.897, p < 0.05$ ), but the interaction between them had no significant effect on the

density of larvae ( $F = 0.302, p > 0.05$ ). There was no significant difference in larval density among different sediments ( $p > 0.05$ , **Figure 4**). The density of larvae increased with the sediment's

organic matter content increase. Over time, the larvae density decreased gradually. There was a significant difference in larval density at different sampling times between sediment 1#, 2#, 4#, and 6# ( $p < 0.05$ ), however, there was no significant difference in other sediments ( $p > 0.05$ ).

## Mortality

The results of two-way ANOVA showed larval mortality not changed through time ( $F = 0.075$ ,  $p > 0.05$ ), independent of type of sediment ( $F = 0.073$ ,  $p > 0.05$ ). The interaction between sediment type and sampling time had no significant effect on larval mortality ( $F = 0.440$ ,  $p > 0.05$ ). No statistically significant differences in mortality were observed among sediments when sampled at the same time point ( $p > 0.05$ , **Figure 5**). The average mortality of larvae was decreasing with the increasing organic content in sediments.

## DISCUSSION

The density of polychaetes in habitat is positively correlated with the sediment's reworking (Duport et al., 2006). The various densities of polychaetes in different regions during the adult stage may be determined at the larval stage's attachment. *P. aibuhitensis* start to feed on monocytic algae when they develop to nectochaeta larvae with three chaetigerous segments (Liu et al., 2005) developed the fourth chaetigerous segment colonize the sediments. In the present study, the density of the *P. aibuhitensis* larvae had no significant difference among

different sediment treatments with different organic matter contents at the initial attachment ( $p > 0.05$ ). It was showed that the *P. aibuhitensis* larvae did not actively make a significant selection on sediments with different organic matter content during the initial attachment stage. However, previous studies found that deposit feeders, including *P. aibuhitensis*, were more inclined to choose higher-energy particles for ingestion (Hylleberg, 1975; Kihlslinger and Woodin, 2000; Fang et al., 2018). Concomitantly, the organic matter contents preference in different sediment were significantly different in this study ( $p < 0.05$ ). Fang et al. (2018) found a threshold of organic carbon content in sediment that decided *P. aibuhitensis* feeding on sediments. The organic content in sediment was about 2.12%, which was enough for the feeding selection of polychaete (Fang et al., 2018). The sediment from the polychaete habitat usually had an organic content higher than 2.2% (Fang et al., 2017), a reference for the present study's design. The experimental treatments' sediment differed significantly in organic matter (all higher than 2.19%). It means that the sediments of the present study could supply enough food to the polychaete larvae. Therefore, in the present study, the *P. aibuhitensis* larvae showed non-selectivity for the sediment with different organic matters, not as the adult *P. aibuhitensis*, which might be due to the organic matter contents of all experimental treatments exceeding the maximum selection threshold of *P. aibuhitensis* larvae. Moreover, polychaetes have an excellent adaption to feeding sediments. Wang and Zhang (1998) showed that the highest feeding rate of *Neanthes japonica* to sediments was conducted under a food-poor environment, which illustrated

that the instinct for feeding and survival of polychaete would be strengthened if the organic matter content was generally low in their habitats. However, environmental conditions in sediments were complicated. The organic matter content and other factors such as the size of the deposit particles (Wang and Zhang, 1998) and the hydrogen sulfide content (Li, 2014) might play important roles in affecting the selection of polychaetes to the sediment. Even if there were some other potential factors, the *P. aibuhitensis* larvae still showed non-selectivity to the sediment with different organic matter content. Passive selection by the environment might make different distributions at the habitat of *P. aibuhitensis*.

*P. aibuhitensis* Larvae will lose its ciliary, step into the creeping stage and begin to feed on the sediment to meet the needs of growth and development after the fourth pair of chaetigerous segments. After that, the larvae preferentially develop functional organs such as sensation, feeding, and swimming, which will benefit survival and proliferation. However, after this period, these organs' growth rate will be significantly slowed down, showing allometric growth patterns (Peter, 1986; Niklas, 1994). In this study, the specific growth rate of larvae in the first month was significantly higher than that of the second and third months ( $p < 0.05$ ), and there was no significant difference in the specific growth rate of the second and third months, which indicated that the *P. aibuhitensis* larvae grew faster during the early period, and then grew slowly. This result was consistent with the allometric growth patterns.

Shi and Zhao (1993) showed that the growth and survival of the *P. aibuhitensis* larvae would decrease if larvae lived in a high density. A 0.35 ind/cm<sup>2</sup> would be a good density

for the growth and survival of larvae. According to the present results, the larvae's density in the initial attachment and first two months was much higher than 0.35 ind/cm<sup>2</sup>. The larvae density was 0.12–0.65 ind/cm<sup>2</sup> in the third month and compared to the initial attachment density of 0.80–1.34 ind/cm<sup>2</sup>, indicating that many larvae died in the early stage. Li (2014) found that the content of sulfide in sediments increased with time. The sulfide content should be higher in sediment with higher organic matter such as 5# and 6# sediment. The *P. aibuhitensis* had a high tolerance for sulfide (Wang et al., 2017). However, the mortality of *P. aibuhitensis* larvae was lower in groups with higher organic matter. Especially in the third month, the density increased with the increasing organic matter content. Hence the sulfide could not be the critical factor for the induced mortality. Only natural habitat and kelp powder were present in the sediment; thus, no additional toxic matter influenced the results. On the contrary, the sediment with high organic matter could provide more food for the larvae, which would support the higher biomass of *P. aibuhitensis* larvae (Hylleberg, 1975; Kihlslinger and Woodin, 2000; Fang et al., 2018). Therefore, the food limitation in the sediment might be the critical factor in the survival of *P. aibuhitensis* larvae.
