A Corrigendum on

Key Determinants of Cell-Mediated Immune Responses: A Randomized Trial of High Dose Vs. Standard Dose Split-Virus Influenza Vaccine in Older Adults

by Verschoor CP, Haynes L, Pawelec G, Loeb M, Andrew MK, Kuchel GA and McElhaney JE (2021)

In the original article, there was a mistake in **Figures 3** and **4** as published. A coding error with the statistical analysis led to erroneous estimates, mainly for associations with the frailty index. Although all estimates were altered slightly, the overall conclusion was not impacted greatly. The corrected **Figures 3** and **4** appear below.

Due to the coding error in the statistical analysis, the description of the findings presented in the **Abstract, Results, and Discussion** could also be misleading.

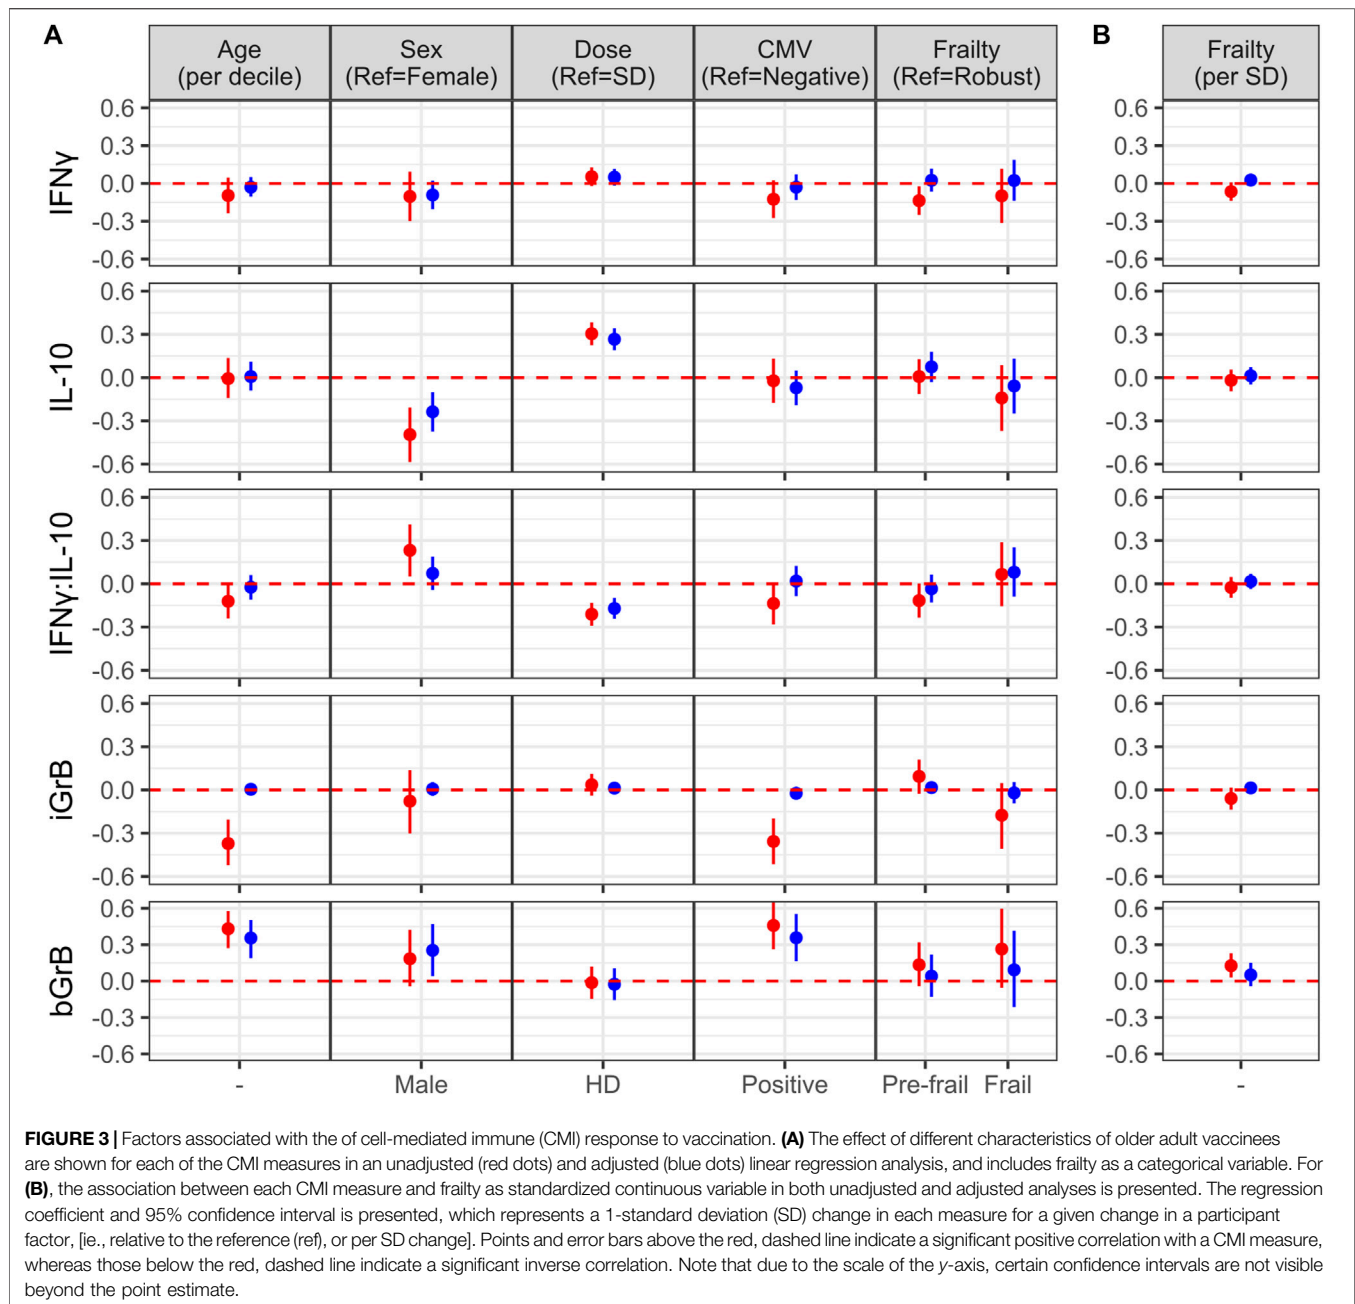

A change was made in the **Abstract**, sub-section “Results,” Line 6. The corrected line now reads: “In a regression analysis, female sex and HD-SVV were associated with higher IL-10 levels, while SD-SVV was associated with lower iGrB levels.”

A change was also made in the **Results**, sub-section “Effects of Age, Sex, Cytomegalovirus Status, Frailty and Vaccine Dose in Older Adults,” Paragraphs 1–3. The corrected text appears below:

RESULTS

Effects of Age, Sex, Cytomegalovirus Status, Frailty and Vaccine Dose in Older Adults

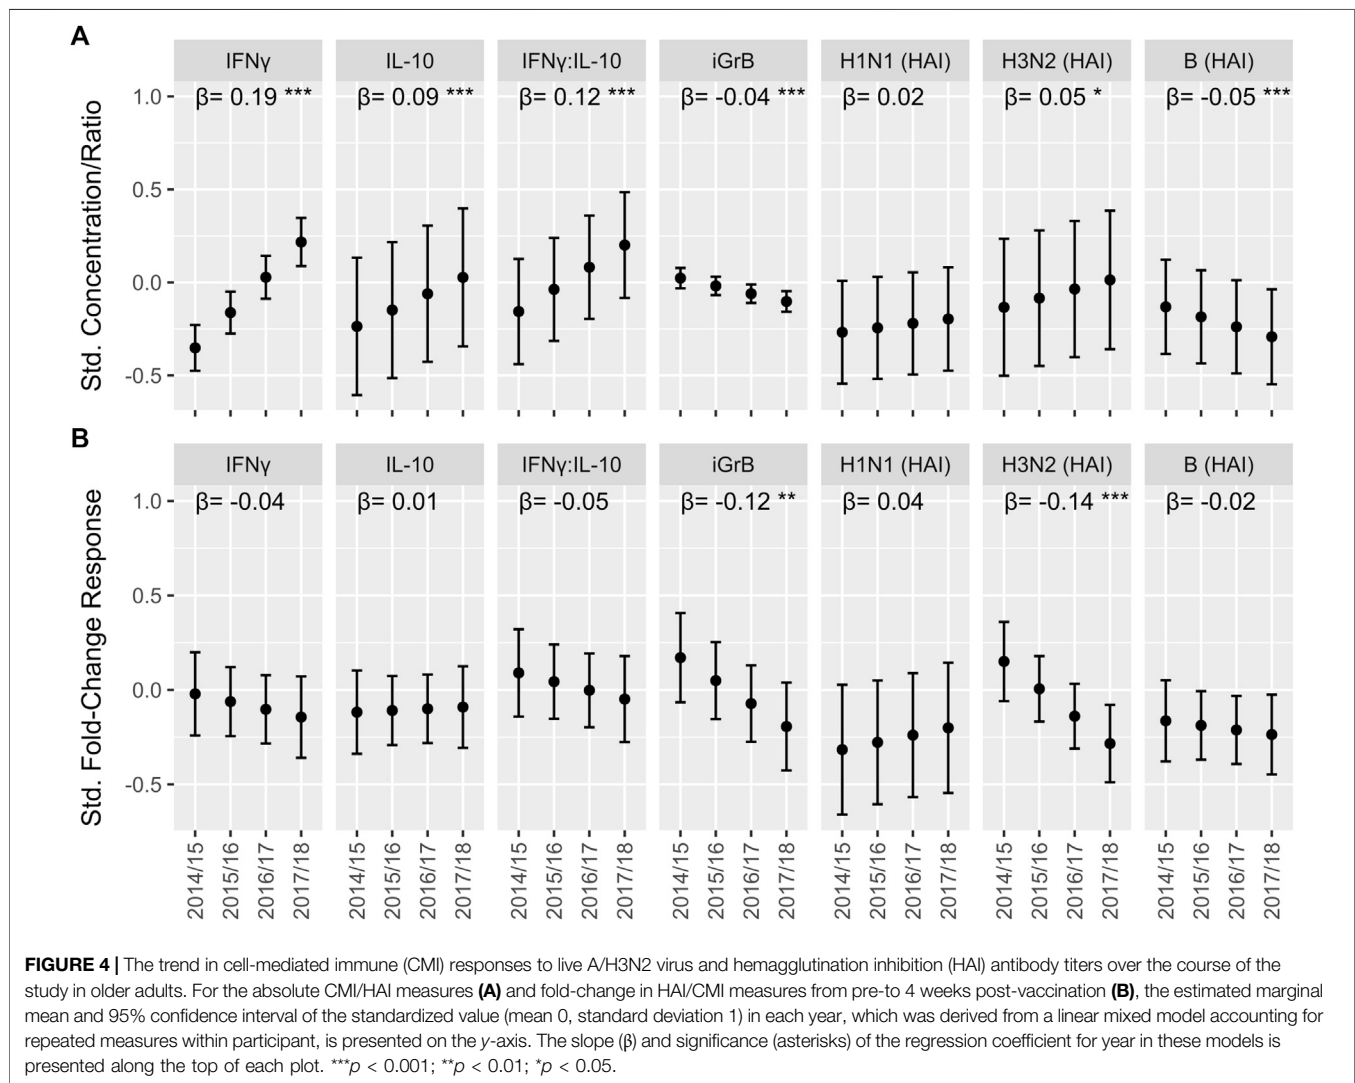

To determine the effect of age, sex, vaccine dose, CMV serostatus and frailty on standardized post-vaccination CMI measures (IFN γ , IL-10, iGrB), we performed linear regression on univariate and

fully-adjusted multivariable models, accounting for the random effect of visit, site, year and participant; the latter was adjusted for pre-vaccination CMI and all aforementioned factors. In fully-adjusted models, IFN γ levels were not significantly affected by age, sex, CMV, dose or frailty (Figure 3). In contrast, IL-10 levels were significantly lower in males vs. females (std. β [95% CI] = -0.24 [-0.37 , -0.10]) and significantly higher in HD vs. SD vaccine recipients (0.27 [0.19 , 0.34]) (Figure 3A). The IFN γ :IL-10 ratio was significantly lower in HD vs. SD recipients (std. β [95% CI] = -0.17 [-0.24 , -0.10]) (Figure 3A). In contrast to measures of the cytokine response to influenza challenge, none of the factors studied affected iGrB levels post-vaccination

(Figure 3). Interestingly, bGrB activity in resting T cells significantly increased with age (std. β [95% CI] = 0.35 [0.19 , 0.50]), male sex (0.25 [0.04 , 0.47]), and CMV seropositivity (0.36 [0.16 , 0.55]) (Figure 3A), while frailty as a continuous variable was not significantly associated (Figure 3B).

We found that the absolute levels of IFN γ (Std. β [95% CI] = 0.19 [0.15 , 0.23]), IL-10 (0.09 [0.05 , 0.13]) and the IFN γ :IL-10 ratio (0.12 [0.08 , 0.16]) increased significantly with each study year, while iGrB levels exhibited a smaller but statistically significant decline (-0.042 [-0.059 , -0.025]) (Figure 4A). In contrast, absolute hemagglutination inhibition (HAI) antibody titers to A/H3N2 (0.049 [0.005 , 0.091]) strains increased significantly while HAI

titers to influenza B declined significantly over the 4 years (-0.054 [$-0.084, -0.023$]) (Figure 4A).

DISCUSSION

Finally, a change was made to the **Discussion**, Paragraph 5, Line 1, which now reads: “In univariate regression analysis, we found that increasing age and CMV seropositivity are significant correlates of the decreased iGrB response to *ex vivo* influenza challenge.”

Paragraph 5, Line 19 now reads: “Our previous studies suggest that the addition of a toll-like receptor (TLR4) agonist to SVV can overcome the suppressive effects of IL-10 and improve the GrB response to influenza challenge (Behzad et al., 2012).”

A change was also made in Paragraph 6, Line 1, which now reads: “In light of the current controversy over the effects of repeated annual influenza vaccination potentially leading to a loss

of vaccine-mediated protection against influenza, we analyzed the effect of vaccination in each study year according to the absolute levels of antibody, cytokines (IFN γ , IL-10, and IFN γ :IL-10) and iGrB at 4-, 10-, and 20-weeks post-vaccination and the pre- to 4-weeks post-vaccination fold-change response in older adults. We found a significant decline over the 4 study years only in the post-vaccination A/H3N2 iGrB levels and influenza B antibody titers.”

The authors apologize for these errors and state that this does not change the scientific conclusions of the article in any way. The original article has been updated.
