Varying solar wind plays a crucial role in the processes inside the magnetosphere. Statistical studies generally reveal the geoeffectiveness of solar wind streams of different origins and types, characterized by various parameters such as dynamic pressure and magnetic field orientation. However, the predictions of the space weather are still not completely reliable. Small-scale structures (observed as highamplitude variations with frequencies above 0.01 Hz) involved in the turbulent flow of the solar wind and in the magnetosheath may contribute to the models' inaccuracies. Spacecraft measurements obtained during last 2 decades provide a great amount of new information about small-scale plasma processes in near-Earth space. However, the influence of solar wind on the dynamics of the smallscale structures in the magnetosheath has been rarely addressed. The present review summarizes experimental studies on this influence including features of turbulence around ion scales. The study aims to give a general picture of the problem and underline the gaps in current understanding of the role of the dynamics of the small-scale structures and turbulence in the solar–terrestrial relations.

KEYWORDS

solar wind, bow shock, magnetosheath, Sun–Earth coupling, turbulence

1 Introduction

Interaction of the supersonic and super-Alfvenic solar wind (SW) flow with the Earth's magnetosphere results in the formation of outstanding bow shock (BS) and a region behind it filled with turbulent shocked plasma—magnetosheath (MSH). The MSH plasma and magnetic field are in contact with the Earth's magnetosphere. Therefore, the analysis of the MSH processes is of great importance for the exploration of solar–terrestrial relations and space weather forecasts.

Predictions of the magnetosphere response on the changing SW parameters are usually based on spacecraft measurements in the Lagrange L1 point [\(Yermolaev et al., 2010;](#page-7-0) [Pallocchia et al., 2006](#page-6-0); [Boynton et al., 2012;](#page-6-1) [Podladchikova and Petrukovich, 2012\)](#page-7-1). These predictions do not account for alteration in plasma and magnetic field parameters in the course of passage from L1 to the magnetosphere, including substantial distortion of the flow in the foreshock region [\(Sibeck et al., 2008](#page-7-2)) and inside the MSH ([Rakhmanova et al.,](#page-7-3) [2015;](#page-7-3) [2016](#page-7-4)) and changes in the magnetic field orientation in front of the magnetopause (Š[afránková et al., 2009](#page-7-5); [Pulinets et al., 2014\)](#page-7-6). This approach provides high reliability only for intensive magnetosphere disturbances such as geomagnetic storms ([Petrukovich et al., 2001\)](#page-7-7). In addition to the statistical approach, models of the solar–terrestrial relations are based typically on MHD descriptions of plasma flow around the magnetosphere ([Spreiter and](#page-7-8)

simulations (adopted from [Omidi et al., 2014;](#page-6-15) figure 10a), (C) hybrid Vlasov simulation (adopted from [Palmroth et al., 2018](#page-7-15); figure 7a (distributed under the terms of the Creative Commons Attribution 4.0 [http://creativecommons.org/licenses/by/4.0/\)](http://creativecommons.org/licenses/by/4.0/), and (D) 2D global hybrid simulation (the bow shock structure is shown, adopted from [Karimabadi et al., 2014;](#page-6-14) figure 13a).

[Stahara, 1980](#page-7-8); [Kartalev et al., 1996;](#page-6-2) [Toth et al., 2005](#page-7-9)). Though the MHD description is of great importance for global understanding of the MSH–magnetosphere system, it cannot reproduce highamplitude small-scale variations [\(Zastenker et al., 2002](#page-7-10); [2008;](#page-7-11) [Hayosh et al., 2006\)](#page-6-3). These variations are characterized by frequencies above 10^{-3} – 10^{-2} Hz and amplitudes above 5–10% and occur throughout the MSH (Němeč[ek et al., 2000](#page-6-4); [Shevyrev et al.,](#page-7-12) [2003;](#page-7-12) [Lucek et al., 2005;](#page-6-5) [Shevyrev and Zastenker, 2005](#page-7-13); [Gutynska](#page-6-6) [et al., 2008;](#page-6-6) [Gutynska et al., 2009](#page-6-7); [Gutynska et al., 2015](#page-6-8)). Moreover, typically, the description of the SW and MSH plasma and magnetic field is based on validity of the frozen-in hypothesis, which may be violated for low-speed plasma in the MSH (see [Antonova et al., 2012](#page-6-9) and references therein). Suggested mechanisms of plasma penetration through the magnetopause include finite gyroradius scattering, diffusion, wave-induced diffusion, impulsive penetration, and magnetic reconnection [\(Sibeck et al., 1999](#page-7-14); [Kirpichev et al.,](#page-6-10) [2017;](#page-6-10) [Fuselier, 2021](#page-6-11)). However, the presence of small-scale variations in the MSH favors additional ways for plasma transport across the magnetopause [\(Echim and Lemaire, 2002;](#page-6-12) [Dmitriev and Suvorova, 2015\)](#page-6-13); therefore, they can affect the

magnetosphere processes. Observed discrepancies between models of the solar–terrestrial relations and reality may be a result of disregarding processes taking place at the scales around and below ion gyroradius (small-scale processes) in the MSH. Recent progress in technology made it possible to use hybrid models [\(Karimabadi et al., 2014;](#page-6-14) [Omidi et al., 2014](#page-6-15); [Palmroth](#page-7-15) [et al., 2018;](#page-7-15) [Lu et al., 2020](#page-6-16)) which can successfully reproduce the basic properties of highly fluctuating MSH environments. [Figure 1](#page-1-0) presents the comparison of the MHD-modeled MSH (panel A, adopted from [Toth et al., 2005](#page-7-9)) with results of three hybrid (electron fluid, kinetic ions) models (panels B–D). Small-scale structures are clearly captured by latter models, demonstrating the importance of their consideration. However, the stochastic nature of turbulent small-scale fluctuations makes them highly irreproducible both for distinct cases and monitoring of the MSH parameters. Therefore, in the exploration of mean characteristics of small-scale structures and turbulence, differences in its features for various background conditions may give information on when the existing forecasts would work well and when they should be corrected to account for processes in the MSH.

For a long time, MSH fluctuations have been considered in a framework of waves ([Anderson et al., 1994;](#page-6-17) [Hubert, 1994;](#page-6-18) [Lacombe](#page-6-19) [and Belmont, 1995](#page-6-19); [Schwartz et al., 1996](#page-7-16)). Great contributions have been made to the understanding of the MSH fluctuations (and are still in progress) with the help of Cluster mission measurements ([Lucek et al., 2005](#page-6-5)). Recent measurements by MMS helped to better understand the small-scale fluctuations and reconnection in the turbulent MSH plasma ([Stawarz et al., 2016;](#page-7-17) [2022;](#page-7-18) [Vörös et al., 2019;](#page-7-19) [Yordanova et al., 2020](#page-7-20)). A number of studies treated the MSH fluctuations in a framework of turbulence (see [Alexandrova, 2008;](#page-6-20) [Sahraoui et al., 2020](#page-7-21); [Rakhmanova et al., 2021](#page-7-22) and references therein). Thus, there is a general understanding of sources, spectral features, and spatial scales of the fluctuations. However, the effect of the varying SW conditions on the properties of the MSH fluctuations was addressed quite rarely.

The present mini-review aims to give an overview of recent studies of the SW influence on the small-scale structures behind the BS. Here, the small-scale MSH structures/variations refer to variations of plasma and/or magnetic field parameters, which are registered by a spacecraft during seconds to minutes. The review does not discuss reconnection, current sheets, waves, and instabilities, however, as this topic is far too large and these have been extensively described before [\(Retinò et al., 2007;](#page-7-23) [Yordanova](#page-7-24) [et al., 2016;](#page-7-24) [2020](#page-7-20); [Khabarova et al., 2021](#page-6-21) and references therein; [Lacombe and Belmont, 1995;](#page-6-19) [Schwartz et al., 1996\)](#page-7-16). Only those studies have been mentioned here, which include observational analysis of the SW influence on the small-scale MSH structures. The authors believe that the review will help find gaps in the exploration of the space weather forecasts and motivate revision of available large datasets of high-quality MSH measurements from this point of view.

2 Basic MSH properties

MSH formation is determined by the interaction of the SW and the magnetosphere. The basic parameter which influences the power of variations behind the BS is the angle between the interplanetary magnetic field and local BS normal— θ_{BN} [\(Greenstadt, 1972;](#page-6-22) [Shevyrev and Zastenker, 2005\)](#page-7-13). For quasi-perpendicular BS $(\theta_{BN} > 45^{\circ})$, the low-energy SW ions (namely, protons and alfa particles, which are dominant in the SW) pass through the BS front and are advected away from it. Generally, the amplitude of the downstream small-scale fluctuations (with frequencies 0.01–1 Hz) is around 7–10% of the mean parameter value in this case ([Shevyrev](#page-7-13) [and Zastenker, 2005](#page-7-13)). For quasi-parallel BS (θ_{BN} < 45°), the SW ions are reflected from the front, go upstream (forming the foreshock region), and are simultaneously advected with the plasma flow to the downstream region. This complex path leads to powerful fluctuations behind the BS. The amplitude of the fluctuations behind quasi-parallel BS is typically twice as high as that behind the quasi-perpendicular BS and reaches 30% for almost-parallel BS $(\theta_{BN} < 10^{\circ})$ [\(Shevyrev and Zastenker 2005\)](#page-7-13). Another well-known difference between the two configurations of the MSH lies in wave activity. At the quasi-perpendicular BS, significant temperature anisotropy $T_{\perp} >> T_{\parallel}$ arises with respect to the mean magnetic field vector. Temperature anisotropy leads to excitation of wave processes and instabilities, with their type depending on local plasma beta

parameter [\(Lacombe and Belmont, 1995](#page-6-19); [Schwartz et al., 1996\)](#page-7-16). Substantial differences in properties of the two configurations of the MSH imply that they should be considered separately to reveal the SW influence on the processes there. The foreshock region, populated with ions reflected from the BS, presents a complex, highly fluctuating, and anisotropic environment in front of the quasi-parallel BS (see [Blanco-Cano et al., 2006](#page-6-23); [Sibeck et al.,](#page-7-2) [2008;](#page-7-2) [Gutynska et al., 2015](#page-6-8) and references in these papers). Effects of the foreshock processes on the downstream MSH variations combine both foreshock intrinsic processes and pure SW effects. For this reason, foreshock processes are not focused on in the present review.

Another property of the MSH parameters is their dawn–dusk asymmetry which partly represents differences of the flow parameters behind the different BS types. A number of studies were focused on the problem of asymmetry in parameters' values and MSH thickness (Němeč[ek et al., 2000;](#page-6-24) [Paularena et al., 2001;](#page-7-25) Němeč[ek et al., 2003;](#page-6-25) [Longmore et al., 2005;](#page-6-26) [Dimmock and Nykyri,](#page-6-27) [2013\)](#page-6-27). Generally, the dusk flank of the MSH is characterized by higher magnetic field magnitude, plasma speed, lower density, and ion temperature than the dawn flank ([Dimmock et al., 2017\)](#page-6-28). Most of the studies suggested SW speed and direction of the IMF to be the main parameters which affect the asymmetry.

3 Properties of the MSH fluctuations for changing SW conditions

A number of studies have tried to reveal if there was a connection between the MSH fluctuations properties and the SW parameters. Němeč[ek et al. \(2002\)](#page-6-24) analyzed statistics of Interball-1 crossing of the MSH at 30-min intervals, which corresponded to fluctuations in the range \sim [0.001–0.01] Hz. The authors showed the fluctuation level weakly depends on the IMF B_z component and not on the SW Alfven Mach number M_A and plasma β. However, a higher level of fluctuations was observed for decreasing the IMF cone angle, which could refer to the influence of the BS topology.

[Gutynska et al. \(2009\)](#page-6-7) presented extensive statistics of magnetic field fluctuations in the frequency range [0.001–0.125] Hz measured by Cluster and analyzed the correlation properties of these fluctuations as a function of the SW parameters. Correlation length of the fluctuations (being 1 R_E in average) was shown to increase significantly for increasing SW velocity, stayed unchanged for different SW densities, and was slightly higher for southward IMF compared to the northward IMF. [Gutynska et al. \(2015\)](#page-6-8) analyzed properties of density transients (density increase by a factor of 1.5 and more during 10–60 s) in the dayside MSH and concluded that they tended to occur during high SW speeds and low densities. The authors also showed preferable occurrence of the structures during low IMF cone and θ_{BN} angles and concluded that density transients were often associated with foreshock processes.

[Dimmock et al. \(2014\)](#page-6-29) studied the influence of the SW velocity and IMF direction on the distribution of the MSH magnetic field fluctuations in the frequency range [0.1, 2] Hz and their dawn–dusk asymmetry based on 6 years of THEMIS measurements. The authors concluded that fluctuations with higher amplitudes were observed for periods of fast SW (with velocities above 400 km/s). Additionally, amplified fluctuations in the vicinity of the magnetopause and

absence of dawn–dusk asymmetry were shown for southward IMF. The authors used a magnetosheath interplanetary medium reference frame ([Verigin et al., 2006\)](#page-7-26) which allowed to account for aberration and for dynamics of the BS and magnetopause positions with variations of the SW parameters.

[Rakhmanova et al.](#page-7-3) [\(2015\)](#page-7-3), [Rakhmanova et al. \(2016\)](#page-7-4), and [Rakhmanova et al. \(2018a\)](#page-7-27) presented a statistical study of the two-point correlation function in the SW and MSH with the help of THEMIS data for density and magnetic field magnitude variations in the range [0.001–0.01] Hz. The authors suggested that the SW variations are more likely to stay unchanged during the BS crossing for higher SW densities and IMF magnitude. Additionally, SW variations with higher amplitudes were shown to be less modified in the MSH. No significant dependencies were found on the SW plasma β, IMF direction, or SW speed.

4 MSH jets and their dependence on the SW parameters

Presence of jets, usually described as transient enhancements of the dynamic pressure or density, is an important phenomenon in the magnetosheath as they can lead to local deformations in the magnetopause and plasma penetration [\(Lemaire, 1977](#page-6-30); [Lemaire](#page-6-31) [and Roth, 1978](#page-6-31); [Dmitriev and Suvorova, 2015](#page-6-13)). There are several causes suggested for their formation including the BS ripples ([Hietala et al., 2009;](#page-6-32) [Hietala et al., 2012](#page-6-33)) and interaction of the SW discontinuities with the BS (Němeč[ek et al., 1998](#page-6-34); [Savin et al.,](#page-7-28) [2004;](#page-7-28) [Savin et al. 2011;](#page-7-29) [Savin et al. 2012](#page-7-30); [Dmitriev et al., 2021\)](#page-6-35). A full overview of the phenomena can be found in [Plaschke et al. \(2018\)](#page-7-31) and [Dmitriev et al. \(2021\).](#page-6-35) Here, we highlight the results referring to the dependence of the jets on the SW parameters.

[Archer and Horbury \(2013\)](#page-6-36) analyzed distribution of the highamplitude transient (during the time intervals [10, 180] sec) enhancements of the dynamical pressure inside the MSH and their dependence on the SW conditions. The authors distinguished two basic regimes characterized by decrease or increase of density. The first group was typically observed during high-IMF cone angles, while the second group occurred predominantly for low-IMF cone angles. For the second regime (the most common), the enhancements were more frequent for increasing solar wind speed, while no dependencies were found on the IMF clock angle, SW plasma parameter β, or Mach number.

[Plaschke et al. \(2013\)](#page-7-32) considered SW conditions favorable for jet formation in the subsolar MSH and concluded that the only significant factor was the IMF cone angle, which implied that the quasi-parallel BS was more favorable for jet formation. The authors used statistics of THEMIS measurements during 2008–2011, i.e., during solar minimum. Thus, the study included limited statistics of high values of the SW parameters such as ion density, speed, and IMF magnitude. Further analysis by [LaMoury](#page-6-37) [et al. \(2021\)](#page-6-37) considered enlarged statistics which covered the years 2008–2018 and showed additional SW parameters favorable for jet formation: SW speed around 300 km/s and 600 km/s, low IMF magnitude and dynamic pressure, high plasma β, and Alfven Mach number. The authors considered separately the SW conditions favorable for jets to reach the magnetopause if they were formed near the BS. These conditions included low-IMF cone angle and plasma β, high values of SW speed, IMF magnitude, and dynamic pressure. Thus, some of the SW properties (namely, the IMF magnitude) may contribute not only to the processes of jets' formation but also to their dissipation in the MSH, and the relative portion of these effects are not clear so far.

The multiple SW factors, which may affect the magnetosphere and MSH, are not physically independent. Typically, their values are grouped according to the type of the SW, e.g., an origin of the SW stream at the Sun ([Yermolaev et al., 2009;](#page-7-33) [Borovsky et al., 2019\)](#page-6-38). Generally, main types of the SW include slow or fast wind, interplanetary coronal mass ejections (ICMEs), and co-rotating interaction regions CIRs (or stream interaction regions, SIRs). In front of the ICMEs or CIRs, compressed regions may be formed (ICME Sheath or CIR Sheath); some of the catalogs of large-scale SW phenomena list them as a distinct SW type ([Yermolaev et al.,](#page-7-33) [2009\)](#page-7-33). Different large-scale flows have varying geoeffectiveness ([Borovsky and Denton, 2006](#page-6-39); [Yermolaev et al., 2012\)](#page-7-34). Recently, the combination of the SW properties started to be considered as driving small-scale MSH processes as well. [Koller et al. \(2022\)](#page-6-40) compared a list of the ICMEs and SIRs with the lists of the MSH jets and found clear differences in the jet's occurrence rate for distinct large-scale SW types. For SIRs and high-speed streams, the number of jets was increased by up to 50% compared to the mean occurrence rate. On the other hand, the occurrence rate was decreased by 50% for ICMEs and associated Sheath regions. The authors noted that the study included only those jets which were aligned with the Sun–Earth line and are, therefore, geoeffective as they reached the magnetopause. This finding uncovers new information on geoeffectiveness of the SW events, as ICMEs and their Sheath regions are typically supposed to cause the most intense magnetospheric response.

5 Role of the large-scale SW streams in dynamics of the small-scale MSH structures

As mentioned in the previous section, large-scale SW structures have different effects on the small-scale MSH variations. However, typically their properties are considered as constant during the flow from the Lagrange L1 point to the magnetopause. At small scales, the plasma and magnetic field variations embedded in the large-scale structures could be modified across the BS and inside the MSH.

[Turc et al. \(2014\)](#page-7-35) presented a study of simultaneous registration of the magnetic clouds (MCs and ICMEs with strong and regular magnetic field) in the MSH based on four representative cases. They have shown that behind the quasi-parallel BS, the smooth rotation of the magnetic field orientation in the MC may be dominated by the MSH variations, which results in difficulties in the magnetosphere response forecasts based on the SW data. Furthermore, [Turc et al.](#page-7-36) [\(2017\)](#page-7-36) presented a statistical study on simultaneous variations of the magnetic field in the MC upstream and downstream from the BS for 82 cases. The B_z component (which is believed to be one of the most geoeffective factors due to the processes of reconnection at the magnetopause) was shown to change its sign in the MSH, sometimes for periods as long as 30 min and more. These cases were observed for the IMF which lay in the equatorial plane. This result corresponds well with earlier results by Š[afránková et al. \(2009\)](#page-7-5) who showed statistical differences between the sign of the B_z component in the SW and MSH. [Turc et al. \(2017\)](#page-7-36) demonstrated that if the predominant IMF component was B_y , both positive and negative B_z could have equal geoeffectiveness.

[Rakhmanova et al. \(2018a\)](#page-7-37) tried to connect the modification of the small-scale plasma structures in the MSH with the type of the upstream SW flow. Their results showed that during slow undisturbed SW, the small-scale SW structures stayed unchanged in the MSH just for 30% of cases. On the other hand, this percentage was higher by the factor of 2 during periods of the CIRs in the SW, that is, small-scale variations inside CIRs tend to survive across the BS. However, for other SW phenomena such as ICME ejecta, the small-scale variations tended to stay unmodified only for half of the cases.

Recently, [Ala-Lahti et al. \(2021\)](#page-5-0) considered passage of the ICME Sheath through the BS. The authors compared magnetic field variations inside the Sheath, registered simultaneously in three points in the MSH, in the SW close to the BS, and at the Lagrange L1 point. The IMF B_z component was shown to be enhanced for a set of substructures, which made them more geoeffective. For some parts of the Sheath, the upstream smallscale structures survived during the transmission through the BS. On the other hand, for other periods, there was no correlation between upstream and downstream variations. The authors showed that variations with frequencies less than 0.01 Hz had increasing probability of surviving during passage through the BS.

Thus, the small-scale MSH structures may evolve in a different way for different large-scale SW types. Statistical relations between the SW parameters and magnetosphere responses often consider the SW type as a parameter. Therefore, an additional study of differences in its effect on the MSH small-scale structures would help improve predictability of the models.

6 SW effects on the features of the MSH turbulence and its evolution

Turbulence of the SW has been proposed to be one of the drivers of the magnetosphere dynamics (see D'[Amicis et al., 2020](#page-6-41) and references therein). Changes in the turbulence properties in the MSH for various SW conditions may be, thus, important for the magnetosphere response on the varying SW flow. Typically, around ion scales, the fluctuation spectra of the magnetic field and ion flux/density are characterized by two power laws with a break both in the SW and MSH; at frequencies lower than the break (MHD scales), the power law exponent (slope) is close to −5/3 (so-called Kolmogorov spectrum), while at higher frequencies (kinetic scales) the slope is around −2.8 [\(Alexandrova](#page-5-1) [et al., 2013;](#page-5-1) [Sahraoui et al., 2020;](#page-7-21) [Rakhmanova et al., 2021](#page-7-22)). Statistical studies demonstrated modification of the shape of turbulent cascade around ion scales at the BS and its restoration at the flanks and near the magnetopause [\(Gutynska et al., 2009](#page-6-7); [Huang et al., 2017a;](#page-6-42) [Rakhmanova](#page-7-38) [et al., 2018b](#page-7-38); [Rakhmanova et al., 2018c](#page-7-39)). These statistical studies addressed the mean parameters and clearly demonstrated non-Kolmogorov scaling at MHD scales at the dayside MSH regions in the vicinity of the BS. However, several case studies [\(Rakhmanova et al.,](#page-7-27) [2020a](#page-7-27); [Rakhmanova et al., 2020b](#page-7-40)) showed differences in the evolution of spectra between two points inside the MSH and different scenarios of the spectrum modification at the BS. The authors have suggested that

turbulent cascade may evolve differently for specific SW conditions. A number of studies considered the influence of the SW parameters on the MSH turbulent spectra. [Gutynska et al. \(2009\)](#page-6-7) showed changes of the mean spectral slopes at the MHD scales from −1.2 to −0.9 with increasing SW velocity. A statistical study [\(Rakhmanova et al., 2020c\)](#page-7-41) showed a tendency to observe typical Kolmogorov scaling at the MHD scales for high-amplitude variations of the SW density and not to observe Kolmogorov scaling for high SW density values. Also, the authors showed that the spectral slope at the kinetic scales tended to deviate substantially from typical values and from theoretical predictions for northward IMF, while for southward IMF, the slope values were around −2.8, usually registered in the SW and MSH. The authors did not find any significant dependence on the SW velocity. On the other hand, [Li et al. \(2020\)](#page-6-43) used MMS statistics and suggested no influence of the SW velocity and IMF B_z value on the evolution of the turbulence inside the MSH.

The preliminary statistical study of [Rakhmanova et al. \(2020b\)](#page-7-40) demonstrated that changes in turbulent cascade at the BS may be influenced by the large-scale SW type. Recently, [Rakhmanova et al.](#page-7-42) [\(2022\)](#page-7-42) presented a set of multipoint case studies, which compared properties of the turbulent spectra in the SW, in the dayside MSH and at the MSH flank, taking into account the plasma propagation delays. The study included 12 cases from three groups of the SW stream types: slow undisturbed SW, ICMEs, and compressed SW (Sheath and CIRs). The results demonstrated that for undisturbed SW, the quasi-perpendicular BS affected the turbulent cascade in a confined region close to the BS, and the shape of the SW spectra restored at the flank MSH. On the other hand, interaction of the disturbed SW streams with the BS always resulted in violation of the Kolmogorov scaling at the MHD scales and in significant steepening of spectra at the kinetic scales in the whole dayside MSH. Interestingly, for the ICMEs, the spectra at the MSH flank tended to have properties similar to those registered in the SW, but for compressed SW flows, the properties of the cascade at the kinetic scales were not restored. This result is demonstrated in [Figure 2,](#page-5-2) where slopes of the spectra in the dayside MSH and in the flank MSH at frequencies higher (P_2) than the ion spectral break are shown *versus* the same slopes in the SW for three groups of the large-scale SW types. The panel on the left demonstrates linear dependence of the turbulence properties downstream from the BS in the dayside MSH on those in the upstream region for the three groups of the SW types. At the flank, the right panel exhibits substantial differences in development of kinetic-scale turbulence for compressed SW flows.

7 Summary

To date, few works were focused directly on the solar wind parameters, which influence the small-scale magnetosheath structures. The present mini-review underlines that

- Varying solar wind conditions contribute to the dynamics of the small-scale structures inside the magnetosheath; however, the contribution of this factor is much less examined than the influence of the foreshock, reconnection, and wave activity.
- IMF parameters (magnitude, B_z component, and cone angle) and ion bulk speed are most frequently reported solar wind parameters, which affect the dynamics of small-scale structures behind the bow shock.

FIGURE 2

Spectral slopes at the frequencies higher than the ion spectral break in the dayside magnetosheath (left) and at the flank (right) versus same slopes upstream from the bow shock for three types of the solar wind; dotted lines show equal values of the downstream and upstream slopes, and magenta dashed line presents the linear fit (adopted from [Rakhmanova et al., 2022;](#page-7-42) figure 6c, d, distributed under the terms of the Creative Commons Attribution 4.0 <http://creativecommons.org/licenses/by/4.0/>).

- Recently, enlarged statistics of high-quality measurements in the magnetosheath helped to find additional factors which contributed to the dynamics of the small-scale structures in the magnetosheath. These factors were plasma density, ion parameter β, and Alfven Mach number.
- Ratio between the contribution of the aforementioned factors and their dependence on each other are still a matter of investigation; complex factors such as type of the solar wind flow may be more perspective for further exploration.

Solar wind parameters contribute to the solar–terrestrial relations not only determining the large-scale dynamics of the magnetosphere system, but through the changes in dynamics of small-scale MSH structures as well. A set of small-scale structures, found with the help of kinetic simulations and reported in the observations, was still not considered in the context of their relation to the upstream solar wind conditions. These structures include magnetic islands [\(Huang](#page-6-44) [et al., 2017b\)](#page-6-44), magnetic holes [\(Huang et al., 2016;](#page-6-45) [Yao et al., 2021\)](#page-7-43), plasmoids [\(Goncharov et al., 2020\)](#page-6-46), and Alfven vortices [\(Alexandrova,](#page-6-20) [2008\)](#page-6-20). A combination of different mission measurements during all parts of the solar cycle is required to get a full picture of properties of the small-scale MSH structures, their sources and contribution to the solar–terrestrial relations. To date, a set of missions with highquality plasma and magnetic field measurements, complemented with realistic simulations, allows for such a complex exploration [\(Dimmock et al., 2020](#page-6-47)). The present review shows what has been achieved and what could be achieved in this scope for understanding the role of small-scale magnetosheath structures.
