Objectives: This systematic review aimed to evaluate the impact of post-stroke exercise-based rehabilitation programs on blood pressure, lipid profile, and exercise capacity.

Methods: Through a systemic search of literature from inception to 2024 using five databases, we analyzed data on the mean difference (MD) using a metaanalysis method to estimate effectiveness.

Results: Thirty-seven randomized control trials were included encompassing various exercises such as aerobic, resistance, stretching, exergaming, robot-assisted training, and community-based training. Significant improvement was illustrated at discharge in systolic [MD 2.76 mmHg; 95% confidence interval (CI) –1.58 to 3.92, P < 0.05] and diastolic (MD 1.28 mmHg; 95% CI 0.54–2.12, P < 0.05) blood pressure and peak oxygen volume (MD –0.29 ml/kg/min; 95% CI –0.53 to 0.05, P < 0.05). We also observed significant improvement at discharge in high-density lipoprotein only after resistance exercise from two articles and low-density lipoprotein only in the intervention groups compared to the control groups from ten articles.

Conclusion: Overall, current exercise-based rehabilitation programs significantly improve blood pressure and exercise capacity in patients with stroke at discharge. However, lipoprotein changes remained inconclusive. Although ameliorative changes were noted in most variables, more research is needed to determine optimum exercise intensity, type combination, and health education to reduce post-stroke complications and mortality.

KEYWORDS

stroke, exercise, blood pressure, lipid profile, neurocardiology

1 Introduction

After a stroke, 75% of patients develop cardiac diseases such as coronary artery disease, myocardial infarction (MI), atrial fibrillation (AF), heart failure (HF), and cardiac dysrhythmias (1-3). Schneck (4) stated that 19% of patients complained of heart problems just 3 months after a stroke, even though they had no history of heart

disease. Several studies also illustrated that cardiovascular disease increased the risk of death after a cerebrovascular accident (4, 5). Among other cardiac cases, coronary stenosis (50%) and MI (3%) were more frequent after stroke (6). Moreover, ventricular arrhythmias, acute MI, HF, and cardiac death can be found among 4.1% of hospitalized patients with intracerebral hemorrhagic stroke, while it increases to 9% among subarachnoid hemorrhagic stroke patients (1). These post-stroke cardiac episodes are caused by stroke-induced heart damage, often known as stroke heart syndrome (7). Therefore, cardiac problems can also occur as a compensatory mechanism for stroke, known as neurogenic stress cardiomyopathy (NSC). Common manifestations of NSC are abnormal electrocardiogram (ECG) waves, ventricular wall abnormalities, and the release of troponin, a cardiac muscle regulator protein (8). Besides NSC, Takotsubo cardiomyopathy is another factor that impairs psychological stress by weakening the heart muscle after a stroke (9). However, cardiac diseases can also develop due to long-term physical inactivity and a sedentary lifestyle (5).

Consequently, 20% of ischemic strokes occur due to several cardiac complications, making cardiac diseases the most common risk factor for stroke (7, 10). When other risk factors, such as hypertension, diabetes, and smoking, are taken into account, people with AF increase their risk of stroke by approximately 5% (10). Moreover, recent studies indicate that approximately 25% of stroke patients without a prior history of AF may develop asymptomatic AF due to cardio-neurogenic mechanisms, increasing stroke recurrence risk and raising mortality by 60% (11). Fortunately, serial 12-lead ECG monitoring within the first month of post-stroke can significantly improve AF detection. However, focusing on persistent sinus rhythm and precise differentiation between AF and ventricular tachycardia are crucial to avoid further risk (12, 13). Evidence from a cohort study demonstrated that after rheumatoid heart disease, 5.2% of the patients had an incidence of stroke (14). Lackland and colleagues (15) found that cardiovascular risk factor prevention was one of the main reasons behind the decline of stroke mortality from third to fourth in the United States. Thus, cardiovascular risk factors prevention after a stroke event is inevitable.

Meanwhile, post-stroke rehabilitation comprises a variety of exercises (muscle strengthening and stretching, mobility training) and education (health education, personal grooming) to improve patients' physical, cardiorespiratory, and cognitive performance (16, 17). Post-stroke blood pressure (BP), cardiac output (CO), heart rate (HR), and heart rate variability (HRV)-the fluctuation between two R waves-levels are essential to determine overall cardiac health and risk of stroke recurrence after rehabilitation (18, 19). Patients with depressed HVR have a lower performance rate, influencing overall recovery (20). A study on 103 subacute stroke patients found an adverse functional outcome following low HRV (18). Studies found that post-stroke cardiorespiratory fitness is not related to the factors causing stroke but to cardiovascular and pulmonary disease (21). The volume of oxygen peak (VO_{2peak}), a measure of cardiorespiratory fitness, drops nearly 50% within a week of a stroke event compared to healthy individuals; although, stroke survivors' often require a higher aerobic capacity to do routine work because of disability (22, 23). The walking ability of stroke survivors also declines due to low VO_{2peak} (22).

Previous meta-analysis studies mainly focus on the impact of aerobic exercise on post-stroke peak oxygen uptake and walking distance; evidence on the effects of post-stroke rehabilitation on cardiac variables and lipid profile was less explored (23, 24). Some meta-analyses illustrated the impact of aerobic exercise on BP and cholesterol levels, but the overall findings were inconclusive due to methodological errors among included studies and outcome measures (20, 25). Furthermore, a metaanalysis conducted by Boulouis and colleagues (26) demonstrated that lowering blood pressure after intracerebral hemorrhage was safe but unrelated to patients' functional outcomes, which debriefed the relation between functional outcomes and cardiac variables after stroke. However, the impact of all types of rehabilitation protocols in intra- and inter-groups and comparing baseline and post-intervention changes on blood pressure, lipid profile, and functional and exercise capacity may provide insight into post-stroke rehabilitation and suggest guidelines to reduce post-stroke complications and mortality.

Therefore, our study aimed to summarize the available evidence on the effect of post-stroke rehabilitation on BP, HR, and CO, lipid profile such as HDL, and low-density lipoprotein (LDL) by comparing post-treatment changes from baseline, as well as changes between control and intervention group. The primary outcomes of our study are BP, lipid profile variables, and exercise capacity (VO_{2peak}), and the secondary outcome is functional capacity (walking).

2 Method

This study followed the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines (27). The protocol of this review is registered and made public in the open science forum (OSF) platform (https://doi.org/10.17605/OSF.IO/X89FW).

2.1 Search strategies and selection of studies

Following PICOS (28, 29) (population, intervention, comparison, outcome, and study design) methodology, a search was conducted in five online databases (Web of Science, PubMed Central, PEDro, Cochrane Library, and Scopus) for studies that reported any of our study variables such as hemodynamic changes, physical function, and cardiorespiratory properties after post-stroke rehabilitation published from inception to June 2024. For PICOS, the population consisted of all patients participating in the post-stroke rehabilitation program. Interventions included any post-stroke rehabilitation program, including exercise and health education. Studies compared the intervention effects on any variables related to cardiovascular or cardiorespiratory and functional changes after the intervention, comparing baseline and

post-intervention changes. The reported study outcomes were any of our study variables such as hemodynamics (BP, HR, and CO), lipid profile variables (HDL and LDL), exercise capacity measured by VO_{2peak}, and functional capacity measured by the 6 min walk test (6MWT). The study design was a randomized control trial (RCT). There was no language restriction on search engines.

The following keywords and medical subject headings (MeSH), and an asterisk (*), to identify associated keywords were utilized for a wide range of search results, such as "Cardi*," "rehab*," "Cerebr*," "Heart (MeSH)," "Brain (MeSH)," "Stroke (MeSH)," "Hemorrhagic (MeSH)," "Exercise (MeSH)," "training," "ischemic," "embolic," "thrombotic," and Boolean/phrase "AND" and "OR." In addition, all relevant article reference lists, previous systematic reviews, and guidelines were screened for selection (shown in Supplementary File 1).

One author (MM) operated the search. Three authors (MM, LX-H, M-LL) screened all articles independently, limiting studies to the following inclusion criteria: (1) study subjects are from post-stroke rehabilitation, including both genders as participants; (2) studies wherein exercise or therapy or training program was performed (such as aerobic exercise, resistance training, community-based rehabilitation program, telerehabilitation, yoga, preventive education); (3) interventional studies, which evaluated the effectiveness of an intervention, with outcomes measured at baseline and post-intervention, with or without follow-up; (4) studies wherein outcome measurement was focused on hemodynamics, lipid profile, and functional and exercise capacity as a primary or secondary outcome, respectively. The exclusion criteria of studies were as follows: (1) studies on subjects having a stroke with other neurological commodities such as Parkinson's disease or Alzheimer's disease, cardiac disease and surgeries such as bypass surgery, and musculoskeletal or traumatic brain injury; (2) studies only focused on stroke without rehabilitation; (3) observational studies (e.g., cross-sectional association or correlation study), case reports, review articles, experimental or animal studies, abstracts, editors or experts' opinions, and letters to editors; (4) unpublished study data or studies that failed to provide outcome data after contact with the author(s). Discussions with the supervising author (HZ) resolved any disputes regarding study selection.

2.2 Screening of article

We utilized reference manager software "Zotero" (30) and "Rayyan" (31) for study screening and finding duplicates. Titles and abstracts were screened for primary selection, and full text and data availability were assessed for final study selection. The author (MM) contacted the respective authors for data availability. Any disagreement was solved through discussion.

2.3 Quality assessment

For the quality of the study and the risk of bias assessment, two authors (MM and W-ZS) utilized "PEDro" (32) and the Cochrane Handbook for risk of bias assessment tool "ROB 2.0" (33). Regarding PEDro scores, studies were categorized as fair (>4), good (6–8), and excellent (9–10). The ROB 2.0 was assessed for the randomization process, deviation from the intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result and categorized as low risk, some concern, and high risk. The leave-one-out forest plot checked for any ambiguity in the study data.

2.4 Data extraction

Two authors (MM and KM) extracted all available data independently from included studies, including first author, year, country, sample size, age, gender, inclusion criteria of participants, type of stroke and disability, rehabilitation programs (such as aerobic exercise, balance training, upper and lower limb exercise, resistance training, health education), standard rehabilitation protocol, treatment duration and intensity, treatment outcomes [BP, CO, HR, HDL, LDL, total cholesterol (TC), triglycerides (TG), FBG, VO_{2peak}, time up and go (TUG), Berg balance score (BBS), 6MWT], follow-up, and summary of all findings (shown in Tables 1, 2).

2.5 Statistical analysis

We analyzed baseline and post-intervention effect data from included studies' hemodynamic changes (BP, CO, HR), lipid profile (HDL, LDL, TC, TG), FBG, functional capacity (6MWT, TUG, BBS), and exercise capacity by VO_{2peak}. We considered each rehabilitation program from a single study as a distinct entry for analysis; we validated the final results of each variable with changes at post-intervention of each study's control and intervention group illustrated by the study's author, followed by the published methodology (34). We used the random effects model of meta-analysis, converted standard error data to standard deviation, and estimated the mean difference (MD) with a 95% confidence interval (CI). A P-value of <0.05 was considered statistically significant. We utilized the software "RevMan" (35) version 5.3 and STATA version 17.0 (StataCorp, College Station, TX, United States) for data analysis. We assessed heterogeneity by the I^2 value (inconsiderable heterogeneity, $I^2 < 0\%-30\%$) and the funnel plot to identify potential outliers (36).

3 Results

3.1 Study selection and screening

A total of 9,484 articles were retrieved, and all duplicate articles were removed. A thorough screening of titles and abstracts excluded 4,855 articles, and 265 articles were assessed for eligibility through full-text analysis. Finally, 37 articles satisfied all the inclusion criteria. The PRISMA flow diagram illustrates the overall search strategy (Figure 1), and the findings of all keywords from electronic databases were tabulated

TABLE 1 Summary of findings of all included articles.

Author, year, country	Total sample size, N	Gender, n (M/F)	Age (mean, SD)	Inclusion criteria on stroke incidence	Type of disability or stroke and severity among included participants, (n)	Treatment duration	Measure(s) and outcome(s)	Follow- up duration	PEDro score
Tang et al., 2013, Canada (49)	50	29/21	59.71, 12.35	 >1 year post-stroke 	 Lacunar, 7 Ischemic, 19 Hemorrhagic, 16 Unknown, 8 	6 months	Aerobic capacity (VO_{2peak}), arterial stiffness, functional capacity (6MWT), hemodynamic and cardiac function (left ventricular ejection fraction, trans-mitral inflow, lateral mitral annulus, right atrial emptying fraction, lateral tricuspid annulus), blood profile (TC, LDL, HDL, triglycerides, fasting blood glucose, homocysteine)	Not estimated	8/10

TABLE 2 Characteristics of included studies rehabilitation program and summary of findings.

Study	Rehabilitation program(s)	Sample size	Age (mean <u>+</u> SD)	Data analyzed	Rehabilitation protocol(s)	Treatment intensity	Treatment duration	Summary of result(s)
Tang et al., 2013_A	Aerobic exercise (AE)	25	65.9 ± 6.4	HDL, LDL, TG, TC, 6MWT, VO _{2peak} , FBG	Walking (overground brisk and inclined), cycle ergometry (upright and recumbent), marching on the spot, repeated sit-to-stand, and step-ups onto platform steppers	High-intensity (40%–70%–80% of HRR)	Total 60 min, 3 times/week	 There were no significant changes in VO_{2peak} in either group (<i>P</i> = 0.45). Improved 6MWT distance (<i>P</i> = 0.02) and reduced total LDL cholesterol and triglyceride levels.
Tang et al., 2013_B	Balance and flexibility (BF)	25	66.9 ± 7.8		Stretching, weight-bearing, postural re- education, and balance exercises	Low-intensity (<40% of HRR)		 No improvement in lipids, glucose, and homocysteine levels and ambulatory capacity
Yim et al., 2014_A	Upper and lower-body exercise with respiratory training	10	54.10 ± 11.69	6MWT	Joint mobility, eccentric contraction, muscle, strengthening, walking exercise, automated full-body workout, and respiratory training	Low-intensity	Total 60 min, 3 times/week	 Increase the mean difference in 6MWT; the walking distance before and after exercise significantly differed between groups.
Yim et al., 2014_B	Upper and lower-body exercise training	10	53.90 ± 5.82		Walking exercise, joint mobility, eccentric contraction, muscle strengthening, automated full-body workout			 Increase shortness of breath modified Borg dyspnea scale before and after exercise in both groups (P<0.05)
Moore et al., 2014_A	Fitness and mobility exercise	20	68 ± 8	Blood pressure, LDL, HDL, total cholesterol, 6MWT, VO _{2peak}	Upper and lower limb stretching, functional strengthening, balance, agility, and fitness training	Moderate intensity, initially 40%– 50% of their maximum HR, increasing increments of 10% every 4 weeks, up to 70%–80%, Strength/balance exercises were progressed by increasing repetitions and loading	45–60 min, 3 times/ week	 Exercise increases work rate and peak oxygen consumption (increased by 17%). A significant within-group increase was demonstrated in diastolic BP in the control group, but between-group differences in resting diastolic but not
Moore et al., 2014_B	Education about health care and stretching	20	70 ± 11		Home-based stretching exercise and health education on medication, diet, and physical activity	Not estimated		 systolic BP in favor of exercise. The exercise group found significant improvement in walking ability, balance, cognition, mood, strength, physical activity, and overall stroke recovery. HDL-C levels increased significantly in the exercise group compared with controls. Total cholesterol, LDL-C levels, body mass index, and composition were unchanged in both groups following the intervention
Moore et al., 2016_A	Fitness and mobility exercise	20	68 ± 8	TUG, CO	Upper and lower limb stretching, functional strengthening, balance, agility, and fitness training	Moderate intensity, initially 40%– 50% of their maximum heart rate, increasing increments of 10% every 4 weeks up to 70%–80%, strength/balance exercises were progressed by increasing repetitions and loading	45-60 min, 3 times/ week	 The exercise group significantly improved peripheral oxygen utilization but did not alter the central oxygen supply. Exercise-induced changes in peak oxygen consumption and peripheral muscle oxygen utilization were not

(Supplementary File 1). PRISMA checklist for the abstract, full text, and other information are available in Supplementary File 2.

3.2 Study characteristics

The characteristics and rehabilitation programs of the included articles were compiled in Tables 1 and 2. The data from 37 trials

(37–73), all intervention and control groups, were illustrated separately in Table 2. In total, 2,337 stroke patients [minimum age of (mean \pm SD) 54 \pm 8.98 years and a maximum of (mean \pm SD) 74.7 \pm 9.3 years] who participated in various rehabilitation programs (minimum duration of 4 weeks and maximum of 24 weeks). The inclusion criteria among articles on stroke incidence among included participants was a minimum of one week to a maximum of a year post-stroke. Ischemic stroke

cases comprised 52.11% (n = 1,218) of all stroke events (Table 1). Moore et al. used the same subjects but reported different variables in two (45, 46) studies in different periods.

Additionally, sixteen articles (37, 38, 40, 41, 43, 44, 49, 53, 55, 57, 63–65, 67, 69, 72) investigated aerobic exercise (such as walking and cycling); six articles (40, 45, 48, 54, 59, 62) compared the effect of health education training; one article (50) included exergaming exercises; one article (70) involved robot-assisted walking training; and three articles (39, 42, 73) involved dynamic and resistance training. Exercise sessions lasted no more than 60 min, were performed three times/week, and were of varying intensity based on ratings of perceived exertion (14–16) and maximum heart rate (40%–95%). Exercise-based rehabilitation programs of all included articles are tabulated in Table 2.

3.3 Risk of bias and study quality

All included articles were evaluated using the "PEDro" and the ROB 2.0 tool. According to the PEDro score, 26 articles (37-41, 45, 46, 48-50, 53-56, 58, 59, 61, 62, 65, 66, 68-73) scored between 6 and 8, which is considered significantly good quality, and the remaining articles were regarded as fair quality (Table 1). None of the articles was excluded due to low quality. Furthermore, only three articles (39, 55, 57) had a high risk, and nineteen articles (42, 46, 48, 49, 53-56, 58, 59, 61, 63, 65, 67-71, 73) had a low risk of bias according to the results of the ROB 2.0 tool. Some concerns were noted in other articles due to the selection of reported results and the randomization process (Supplementary File 3).

3.4 Post-rehabilitation changes in BP, HR, and CO

From 19 articles (37-40, 44, 45, 48, 52, 54, 57-62, 64, 68, 69, 72), we analyzed stroke patients' SBP from baseline (number of patients, n = 1,146) and after discharge (n = 1,144). Cumulative results showed that the reduction of SBP after discharge was significant (MD 2.75 mmHg; 95% CI 1.58-3.92; P < 0.05, $I^2 = 0\%$), similar results were found in the comparison of baseline and discharge changes between control and intervention group (P < 0.05) (Figure 2), but the subgroup analysis of aerobic exercise, resistance training, and standard care from baseline to discharge shows insignificant reduction but tends to be positive effect (Supplementary File 4A). Notably, diastolic blood pressure (DBP) from baseline (n = 1,173) and after discharge (n = 1,168)from 18 articles (37-40, 44, 45, 48, 52, 54, 57-62, 68, 69, 72) showed significant declination (MD 1.28 mmHg; 95% CI 0.45-2.12 mmHg; P < 0.05, $I^2 = 0\%$), but in the comparison of baseline and discharge changes between control and intervention group, this improvement was insignificant $(P > 0.05, I^2 = 0\%)$ as well as from all subgroup analysis (Supplementary File 4B). We analyzed stroke patients' physiological variables (such as HR and CO) to find insightful explanations for these challenges. We found postrehabilitation HR changes from eleven articles (38, 39, 44, 52, 56, 57, 60, 61, 64, 68, 72) (Figure 3) and CO changes from three articles (41, 45, 46) (Supplementary File 5) at discharge, and the comparison of baseline and discharge changes between the control and intervention group was insignificant (P > 0.05) but ameliorative. However, concerning the positive impact of rehabilitation, our study recommends modification of post-stroke rehabilitation protocol in terms of exercise intensity, duration, and frequency to have a significant outcome.

3.5 Post-rehabilitation changes in lipid profile

We analyzed HDL from 12 articles (38, 40, 44, 45, 48, 49, 52, 54, 58, 62, 69, 73) (n = 750) at discharge [MD -0.02 (95% CI -0.05 to 0.01), P > 0.05, $I^2 = 0\%$], and the comparison of baseline and discharge changes between the control and intervention group [MD -0.04 (95% CI -0.10 to 0.02), P > 0.05, $I^2 = 0\%$] was insignificant (Supplementary File 6A). However, subgroup analysis at discharge on resistance training found significant changes [MD -0.18 (95% CI -0.22 to 0.14), P < 0.05, $I^2 = 0\%$] (Figure 4A). LDL from nine articles (37, 40, 44, 45, 48, 49, 52, 62, 73) (n = 659) at discharge [MD 0.01 (95% CI -0.08 to 0.09), P > 0.05, $I^2 = 0\%$] and subgroup analysis at discharge was insignificant (Figures 4B,C). Further, the comparison of baseline and discharge changes between the control and intervention group found significant changes [MD 0.18 (95% CI 0.06-0.29), P < 0.05, $I^2 = 0\%$] (Figure 4D). These changes suggest that all intervention groups' exercise may have had a higher impact due to the type of exercise combination than those of control groups at discharge, which requires further validation using cross-over control trial methods. TC from 10 articles (37, 38, 40, 45, 49, 52, 54, 58, 61, 73) (n = 491) found insignificant improvement at discharge and between groups (P > 0.05) (Supplementary File 7). Nonetheless, TG from six articles (37, 49, 52, 62, 69, 73) (n = 399) found significant improvement at discharge [MD 0.10 (95% CI 0.01–0.18), P < 0.05, $I^2 = 0\%$] (Supplementary File 8A). Furthermore, the comparison of baseline and discharge changes between the control and intervention group found insignificant changes [MD 0.10 (95% CI -0.04 to 0.24), P < 0.05, $I^2 = 0\%$] (Supplementary File 8B).

3.6 Exercise and functional capacity after rehabilitation

Post-rehabilitation exercise capacity was assessed via VO_{2peak} after exercise from nineteen articles (37, 40–42, 44, 45, 49, 53, 55, 56, 60–66, 70, 71) (n = 710) and found significant changes at discharge [MD -0.29 ml/kg/min (95% CI -0.53 to -0.05), P < 0.05, $I^2 = 0\%$], although insignificant changes only after health education (P > 0.05), but the inclusion of health education with standard care and exercise-based rehabilitation was found to have a positive effect. However, a significant improvement was found in the comparison of baseline and discharge changes

between the control and intervention group [MD -2.27 ml/kg/min (95% CI -3.01 to -1.54), P < 0.05, $I^2 = 0\%$] (Figure 5).

Post-stroke rehabilitation significantly improved functional capacity measured in 6MWT from 12 articles (42, 43, 45, 49,

50, 53, 55–57, 60, 63, 66) (n = 448) and found significant changes at discharge [MD -27.15 m (95% CI -45.11 to -9.18), P < 0.05, $I^2 = 49\%$], but the comparison of baseline and discharge changes between the control and intervention group

post-stroke rehabilitation programs. SBP, systolic blood pressure; DBP, diastolic blood pressure; SD, standard deviation; IV, inverse variance; CI, confidence interval; df, degree of freedom.

found insignificant changes [MD -13.61 m (95% CI -39.95 to 12.73), P < 0.05, $I^2 = 31\%$] (Supplementary File 9). Furthermore, BBS (n = 123) improved significantly at discharge than baseline [MD -3.39 (95% CI -5.04 to -1.75), P < 0.05, $I^2 = 52\%$], as well as changes between control and intervention groups from one article (45) (n = 40) (P < 0.05) (Supplementary File 10).

Contrarily, TUG (39, 46) (n = 62) test has an insignificant change after post-stroke rehabilitation at discharge [MD 1.76 (-0.49 to 4.01), P > 0.05, $I^2 = 0\%$] and the comparison of baseline and discharge changes between the control and intervention groups [MD 2.67 (-0.81 to 6.14), P > 0.05, $I^2 = 0\%$] (Supplementary File 11). These results suggest an

overall deterioration in functional outcomes in different measures. In line with previous studies, our study also emphasizes that standardized and personalized measurement tools must be developed to prescribe exercise for people with stroke, concerning exercise principles such as specificity, overload, and reversibility for better outcomes (74).

Furthermore, FBG from seven articles (38, 48, 49, 54, 58, 62, 73) (n = 544) found significant changes at discharge [MD 0.15 (95% CI 0.04–0.26), P < 0.05, $I^2 = 0\%$] and the comparison of baseline and discharge changes between the control and intervention group [MD 0.17 (95% CI 0.03–0.30), P < 0.05, $I^2 = 0\%$] (Supplementary File 12). Moreover, homocysteine level

changes from two articles (48, 49) (n = 87) found an insignificant (P > 0.05) improvement after the post-stroke rehabilitation program (Supplementary File 13).

3.7 Publication bias and sensitivity analysis

We analyzed publication bias (75) using the funnel plot for variables, which included over ten studies; none of our results presented potential bias (shown in Supplementary Files 4, 6, 8, 10, 11). Sensitivity analysis (76) was done using the leave-oneout method. If any studies significantly impact overall results on

any variables, we excluded that study from the analysis. Moreover, our findings suggest that all post-rehabilitation interventions enact no potential risk on outcomes.

4 Discussion

This systematic review and meta-analysis sought to evaluate the extent to which a rehabilitation program impacts cardiac health (BP, HR, and CO), lipid profile variables (HDL and LDL), exercise capacity (VO_{2peak}), and functional capacity (6MWT) in patients after stroke. We included all RCTs that evaluated these changes among stroke survivors at any stage. Using the

meta-analysis method, we analyzed the outcome data for the mean difference at discharge from baseline from all groups and changes (baseline to post-intervention) at discharge between control and intervention groups. The results of all variables at discharge are graphically presented in Figure 6. This result provides a comprehensive conclusion on the overall exercise-based rehabilitation programs practiced for patients with stroke. Notably, our study indicated that, whereas BP, functional, and exercise capacity improved significantly following rehabilitation programs, lipid level control was insignificant but ameliorative. These findings support modifying the post-stroke rehabilitation protocol and prioritizing cardiac health as a surrogate measure of rehabilitation outcome.

BP reduction is vital to controlling stroke risk factors (26). Numerous pieces of evidence stated that >5.2 mmHg reduction of SBP can reduce the odds of having a recurrent stroke by up to 22% (77). Among combined exercise training groups, SBP and DBP reduction was significant. However, subgroup analysis showed an inconsistent effect, supporting both findings from a Cochrane review among 2,797 patients and a meta-analysis, which compared only aerobic exercise effects after rehabilitation and found an inconsistent effect on SBP and DBP (77, 78). Our analysis indicates that the underlying reason for this inconsistency could be the effect of exercise intensity. A recent RCT study emphasized that the intensity of training programs during stroke rehabilitation is pivotal to improving cardiac health and functional capacity (79). High-intensity treadmill training at a peak heart rate of 85%-95% (40) and high-intensity aerobic exercise training (brisk walking, cycling, marching) among 50 stroke patients showed significantly improved functional capacity (49). Nevertheless, growing evidence suggests that exercise intensity and exercise-induced fatigue burden patient recovery during rehabilitation (20).

HR is a precursory variable for assessing and reducing cardiovascular risk factors (80). After ischemic stroke, a higher HR at baseline correlated to higher cardiovascular risk and mortality (81). Mean HR increased to 10 beats/minute (bpm) from baseline (60 bpm), increasing the cardiovascular risk hazard ratio to approximately 0.39 (82, 83). Thirty-day mortality increases by 2.5% in ischemic stroke patients with atrial fibrillation for mean HR increases each one bpm over 80 bpm (81). HR and HRV changes occur inversely (84). Nozoe et al. illustrated that early mobilization after an ischemic stroke would cause neurological deterioration, which diverges the sympathetic nervous activity to affect HRV, identified by the fraction of low frequency and high frequency (19). In clinical practice, to identify and adjust the HRV to find the best possible training program for a stroke patient, a new training method called "the self-generate physiological coherence system" was designed based the brain-heart interaction and pressure concept, on demonstrating higher recovery and patient satisfaction (20). Our findings, backed by other studies, found that after a rehabilitation program, the resting HR of stroke patients decreased insignificantly (18, 80). These findings suggest that to develop a personalized rehabilitation program, one needs to focus on HRV and plan to decrease resting HR.

Furthermore, increased HDL reduces the risk of ischemic stroke (85). Conversely, an LDL level of <3.9 mmol/L after stroke can minimize cardiovascular risk (86). Our study is in line with previous findings that the reduction of LDL and TC and improvement of HDL are insignificant after post-stroke rehabilitation (25, 77). However, we found that after resistance exercise, HDL improvement was significant. Yang and colleagues (87) found a robust correlation between a decrease in total cholesterol/HDL ratio and an increase in VO_{2peak}, although the level of evidence was reported as low. Our meta-analysis of four RCTs on post-stroke rehabilitation reported an improvement in VO_{2peak} in comparing baseline and discharge changes between the control and intervention group in MD -2.97 ml/kg/min

(95% CI –3.01 to –1.54). This finding is similar to two other meta-analyses, 1 of 13 RCTs in MD 2.53 ml/kg/min (95% CI 1.78–3.29) and another of 12 RCTs in MD 2.27 ml/kg/min (95% CI 1.58–2.95) on cardiorespiratory fitness in stroke patients' after exercise (88, 89). Therefore, 1 ml/kg/min of VO_{2peak} improvement reduces 15% of mortality risk among coronary artery patients (90). However, mortality risk after stroke increases by elevated HR rather than the level of VO_{2peak} of patients with stroke (81). Furthermore, a Cochrane review stated that cardiorespiratory fitness training is feasible for the stroke population and improves walking capability and balance (78). Our findings also showed that stroke survivors covered significantly greater walking distances in 6MWT and BBS scores improved after rehabilitation.

Improving health-related knowledge among stroke patients can also improve their cardiac health (91). One of our included studies used an Android health application among 1,299 stroke patients to remind them about a healthy lifestyle through voice and text message services. Significant improvements in their cardiac health, such as BP and lipid profile, were found (51). A nurse-led health education study, including 268 patients, showed similar findings (47). Furthermore, In line with previous studies, specific exercisebased rehabilitation (aerobic, resistance) can sufficiently improve post-stroke blood pressure and functional or exercise capacity; yet, the improvement on some cardiac variables (HR, CO) or lipid profile variables (LDL, TC) is still inconclusive (55, 57, 64, 73). A growing number of RCT studies compared the effects of exercise-based rehabilitation with sham groups, while the intervention group exhibits a higher impact due to program design (55, 65, 72). To alleviate these, we recommend more crossover randomized control trials on our study variables among poststroke patients. However, answering the root cause of this decline is beyond our study objectives; more fundamental studies on the mechanism of NSC are recommended, as mentioned before. Thus, our study, in line with other meta-analyses, suggests that aerobic exercise has higher benefits than other exercise training and should be included as a fundamental exercise program for stroke survivors (23, 25).

Moreover, Stoller and colleagues (70) experimented with robotassisted training and illustrated that the recommended intensity is not consistently achievable among stroke patients. Increasing exercise repetition might positively impact stroke patients' exercise outcomes (92), which requires robust evidence from clinical studies. Some studies mentioned that the HRR was at a high-intensity level (70%–85%); the evidence is still disseminated to determine the optimal exercise intensity level for stroke patients (54–56, 62). Nonetheless, during follow-up, the impact of exercise was found to have a deterioration than at the discharge level (54, 62), which may hinder overall health among stroke survivors; practicing health education (40, 59, 62) and home-based (38, 48, 69) and community-based (42) exercise programs might be beneficial and improve post-stroke QoL and mortality.

Eventually, we recommend further studies in a large cohort in a randomized and cross-over control trial setting using modern technology such as a smartwatch and functional nearinfrared spectroscopy to compare exercise with different intensities and repetition with health education with long-term follow-up to find the rehabilitation effects on cardiac health. A meta-analysis is required to find different exercises that impact blood pressure changes and report the risk of fatigue, syncope, and mortality rate.

4.1 Limitation

Post-stroke rehabilitation intensely focused on the functional outcome rather than cardiac health, which led to the inclusion of fewer articles on our study topic. Our study selection criteria were not limited to treatment methods, intensity, or the stroke timeline, which generalizes our findings on rehabilitation practice. Due to data unavailability, we could not include all studies in all variables during the meta-analysis; a subgroup analysis on the time of stroke incidence and the impact of exercise was also unattainable. Considering the significance of hemodynamic changes among this population, we suggest that future research on the effect of post-stroke rehabilitation should report changes in the hemodynamic variables as reciprocal measures.

5 Conclusion

Our study revealed that current exercise-based rehabilitation programs significantly improve blood pressure and exercise capacity in patients with stroke at discharge. However, lipoprotein changes remained inconclusive. Although ameliorative changes were noted in most variables, more research is needed to determine optimum exercise intensity, type combination, and health education to reduce post-stroke complications and mortality.
