¹Carbon Upcycling Technologies, Calgary, AB, Canada, ²Department of Chemistry, University of Calgary, Calgary, AB, Canada

Carbon dioxide removal (CDR) is an essential feature of climate mitigation. With current techniques falling short in terms of performance, cost, and environmental integrity, novel CO₂ utilization has the potential to create a multi-billion dollar commodity market that is capable of sequestering large amounts of CO₂ from the atmosphere. To achieve this, significant development in terms of government funding, policy change, and research is needed. This review highlights the current state of novel CO₂ utilization technologies. The paper evaluates their future prospects by drawing parallels with two successfully developed hardware-heavy technologies of the last 50 years, namely the solar and the automobile industries. Both technologies have had radically different commercialization pathways, and offer important insights on facilitating and accelerating the development of novel CO₂ utilization technologies to meet critically relevant climate targets.

Keywords: carbon dioxide removal techniques, carbon capture, carbon storage, carbon utilization, climate change mitigation

INTRODUCTION

Scientific and historical evidence considered by the Intergovernmental Panel on Climate Change (IPCC) (IPCC, 2014) and the National Aeronautics and Space Administration (NASA) (NASA, 2008a) has illustrated a perpetual increase in atmospheric carbon dioxide (CO₂) levels from the pre-industrial times to the present day. With high confidence, this anomalous occurrence has been related to anthropogenic activities (IPCC, 2014; Prentice et al., 2019). The result has been an increase in global temperatures by 0.8°C since the inception of the industrial revolution (IPCC, 2014; NASA, 2008b). Continual global warming is expected to change rainfall patterns and cause extreme weather events (Wheeler and Von Braun, 2013), thereby adversely impacting the distribution of crop yields (Wheeler and Von Braun, 2013), fish populations (Sharma et al., 2011), and freshwater resources (Arnell and Reynard, 1996).

The Paris Agreement (Paris Agreement, 2015) was signed by the Conference of Parties in 2015 to prevent further climate effects by designing and implementing strategies to limit global temperature rise to less than 1.5°C by the end of this century. This objective implies reaching net zero CO₂ emissions on the global scale by the year 2050 (Rogelji et al., 2018). Achieving this target would entail significant reductions in global CO₂ emissions associated with the energy and agricultural sectors, as well as major industrial segments such as cement and steel production (Rogelji et al., 2018). The decarbonization of electricity supply at an industrial level and the use of electric appliances at the consumer level are also required in reducing CO₂ emissions (Rogelji et al., 2018). Another element imperative to achieving net zero CO₂ emissions is the institution of Carbon Dioxide Removal (CDR) techniques (Rogelji et al., 2018).

CDR is an umbrella term used to describe a range of techniques that serve to remove/sequester CO₂ from the atmosphere in order to maintain or reduce its levels and ultimately prevent or reverse

TABLE 1 | An abridged list of CDR techniques analyzed by the IPCC for their CO₂ removal potential in gigatons and the associated costs on an annual basis. Several studies providing a range of values for cost and potential for each technique were considered, however values reported by Fuss et al. were deemed the most realistic estimations by the IPCC.

CDR technique name	Type	Cost (USD per ton of CO ₂ equivalent removed)	Potential (GtCO ₂ removed per year)
Afforestation/reforestation	Natural CO ₂ utilization sink	5–50	0.5–3.6
Biochar and soil sequestration	Advanced natural CO ₂ utilization sink	30–120	2.3–5.3
Enhanced weathering	Advanced natural CO ₂ utilization sink	50–200	2–4
Direct air capture with storage	Artificial CO ₂ storage	100–300	0.5–5
Carbon capture and storage	Artificial CO ₂ storage	100–300	0.5–5
Biomass energy with carbon capture and storage	Advanced natural CO ₂ utilization sink	100–200	0.5–5

CDR, carbon dioxide removal; IPCC, Intergovernmental Panel on Climate Change.

the impact of CO₂ associated with climate change (National Research Council, 2015; Mach et al., 2014; Masson-Delmotte et al., 2018). Such techniques fall along a spectrum of approaches that remove CO₂ by i) enhancing carbon utilization sinks already present in nature such as reforestation or afforestation; ii) creating advanced natural carbon utilization sinks in the soil (e.g., sequestration and biochar) and the ocean (e.g., enhanced weathering and marine algae farming (Chung et al., 2011)); and iii) engineering technologies such as Carbon Capture and Storage (CCS) or Direct Air Capture (DAC) that serve to remove and artificially store away atmospheric CO₂ in geological reservoirs (National Research Council, 2015; Mach et al., 2014) (Table 1). Additionally, techniques such as Biomass Energy with Carbon Capture and Storage (BECCS) remove CO₂ through the creation of biomass which can then be utilized to generate carbon-based forms of energy such as biofuels (National Research Council, 2015; Mach et al., 2014; Consoli, 2019).

CDR techniques have been an essential part of the climate mitigation-focused Integrated Assessment Models (IAMs) designed by the IPCC, which show a range of possible mitigation pathways that limit global warming to 1.5°C (Masson-Delmotte et al., 2018). More stringent pathways assume a significant reduction in energy demand and approximate a complete switch to renewable energy, whilst less stringent pathways are decidedly dependent on CDR techniques. Importantly, the realistic pathways are characterized by reduced stringency on energy and agricultural demand curtailment alongside increased adoption of CDR techniques (Masson-Delmotte et al., 2018). As the scenarios decrease in stringency, the cumulative requirement for CO₂ removal increases from 0 Gt to 1,218 Gt by 2100 (Masson-Delmotte et al., 2018).

Widespread adoption and further development of CDR technologies as an inevitable part of the prospective global pathway of reducing CO₂ levels is persuasive, as the International Energy Agency's (IEA) business-as-usual scenario projects energy demand rising by an average of 35% by 2040 (IEA, 2018), whilst requirement for agricultural goods is estimated to rise by 50% in the year 2030 (Wheeler and Von Braun, 2013). As population growth and a consumption-focused lifestyle increases (Rogelji et al., 2018), CDR techniques are being recognized as more prominent climate change mitigation solutions. At the forefront are technologies such as CCS, DAC,

and BECCS due to their potential for scalability and long term CO₂ storage (Page et al., 2019).

However, several challenges ranging from high capital and operating costs; low practical carbon reduction/sequestration capacities; ecological side effects; performance uncertainties; low Technology Readiness Levels (TRL, is a measurement of the maturity of a technology, the levels range from 1 to 9 and technology maturity increases with the level numbers (Beck, 2013)); a lack of globally enforced carbon regulation, as well as a lack of feasible scale of deployment, have plagued the development of CDR technologies (National Research Council, 2015; Ciais et al., 2013; Field and Mach, 2017; de Coninck and Revi, 2018). For example, afforestation/reforestation and fertilization of land plants have limited carbon sequestration capacities and short timescales of CO₂ storage that range from decades to centuries (Read and Royal, 2001; Ciais et al., 2013; Field and Mach, 2017). Whilst CCS and DAC offer long timescales of CO₂ storage ranging in millennia, they are expensive techniques causing limitations to large scale deployment (Ciais et al., 2013; de Coninck and Revi, 2018). Enhanced weathering can cause permanent pH changes (Ciais et al., 2013) to the ocean and soil, whilst BECCS requires extensive land use that can negatively affect biodiversity (Allen et al., 2018).

Hence, a new family of CDR technologies that utilize atmospheric CO₂ in a feedstock mix for producing value-added, industry-sought commodities are gaining traction as a cost-effective and economically driven CDR pathway (Sandalow et al., 2017; Norhasyima and Mahlia, 2018; Hepburn et al., 2019; Zhu, 2019). In recent literature, these technologies have been defined under the broad spectrum of CO₂ utilization, which also includes techniques such as forestation, biochar production and Enhanced Oil Recovery (National Research Council, 2015; Norhasyima and Mahlia, 2018; Hepburn et al., 2019; Zhang et al., 2020; Baena-Moreno et al., 2019). We propose the term “novel CO₂ utilization technologies” to classify this family of CDR technologies and define it as the utilization of atmospheric CO₂ in a feedstock mix for producing commodities such as materials and chemicals for commercial and industrial use. By fabricating value added, industry-sought commodities from a feedstock of CO₂ emissions, large scale deployment that can have the potential of causing a dent in the CO₂ emissions is made feasible.

In recent years, several institutions and programs such as the US Department of Energy; the NRG COSIA Carbon X-PRIZE; Natural Resources Canada; and Emissions Reduction Alberta have expressed interest in the development of new technologies that utilize CO₂ emissions through the allocation of funding and grants. Independent companies and start-ups that incorporate captured CO₂ emissions into their feedstock for polymers and concrete, such as Covestro and Carbon Upcycling, are also emerging. The importance of such technologies in the context of climate mitigation is being increasingly recognized, however their full-scale impact is still under investigation.

In this paper we move beyond the range of popular CO₂ utilization techniques found in contemporary literature such as forestation, biochar, and BECCS to discuss novel CO₂ utilization in the context of the CO₂ industrial commodity market. The purpose is to provide a discussion for facilitating rapidly scalable, scale-relevant, and market-driven pathways for the CO₂ commodity market.

This is done by studying the conditions required and the associated challenges for the development and scaling of novel CO₂ utilization technologies for the purpose of determining their prospects in the context of climate mitigation. Through an overview of the examples of successful commercialization and global scale achieved by the solar and automobile industry, we present a set of guidelines that will aid the growth and widespread implementation of novel CO₂ utilization technologies. The intent is to elucidate contrasting evolutionary pathways of two other hardware-intensive industries from the industrial age as a way to provide a perspective to policy makers, innovators, corporations, and other entities in the ecosystem seeking to devise or contribute to a pathway to develop, scale, and commercially deploy novel CO₂ utilization technologies today.

CARBON DIOXIDE REMOVAL TECHNIQUES IN CONTEMPORARY LITERATURE

As previously mentioned, CDR techniques ranging from the simple forestation methods to the more progressive carbon capture technologies have been developed and studied in the literature for their cost and capacity to mitigate climate change (Mach et al., 2014; de Coninck and Revi, 2018). Their associated ecological side effects and performance abilities have also been studied in depth (Russell et al., 2012; Keller et al., 2018; McCormack et al., 2016). **Table 1** summarizes the costs and CO₂ removal capacities for a range of CDR techniques found by Fuss et al. (2018) and published by the IPCC.

In order to achieve net zero CO₂ emissions by 2050 and consequently maintain global warming at 1.5°C, CDR techniques need to remove 37–40 GtCO₂ per year starting in 2020; with rates only increasing annually from there onwards (Bui et al., 2018; Haszeldine et al., 2018; Masson-Delmotte et al., 2018). Evaluating the global estimated land available for afforestation/reforestation, a 0.5–3.6 GtCO₂ per year removal capacity could be expected, which is insufficient to offset the required CO₂ emissions in time

for 2050. Additionally, a large water footprint is predicted for afforestation/reforestation techniques, with CO₂ eventually being released back into the atmosphere after a few decades to centuries (de Coninck and Revi, 2018). In the discussion for CO₂ sequestration through soil, the production of biochar is well documented. Biochar is a stable alternate form of biomass that has a slower rate of decay and can be added to soils to enhance their carbon sequestration capacity (National Research Council, 2015; de Coninck and Revi, 2018). Although soil sequestration is inexpensive, biochar production comes with heavy costs and potential impacts on the carbon cycle (Ciais et al., 2013).

Traditional techniques that involve reformed land practices for increased CO₂ utilization through fertilization of land plants are important in decarbonizing the agriculture sector. However, these methods along with micro/macro algae farming are not a permanent source of CO₂ storage as decomposition will eventually lead to CO₂ returning back into the atmosphere (Read and Royal, 2001; de Coninck and Revi, 2018). Another technique that utilizes CO₂ is the enhanced weathering process of rocks in the oceans that converts atmospheric CO₂ to solid carbonates. Given optimum rock type, weathering rate and available area, this technique exhibits a high potential for CO₂ storage (Strefler et al., 2018). However, enhanced weathering of rocks can cause several unintended ecological side effects such as the aforementioned changes in pH and the release of heavy metals into the environment (de Coninck and Revi, 2018; Strefler et al., 2018).

Advanced technologies that extract anthropogenic CO₂ have been widely studied and explored for their role in the climate mitigation discourse. The CCS system removes CO₂ emissions from point sources, such as combustion power plants and industrial facilities (Metz et al., 2005). Once the CO₂ is separated from the gaseous matrices, it is compressed to high densities for ease of transportation and subsequent geological or ocean storage (Metz et al., 2005). The DAC technology focuses on removing CO₂ gas directly from the ambient atmosphere (National Research Council, 2015; de Coninck and Revi, 2018; Haszeldine et al., 2018). Large scale deployment of both techniques is limited by the availability of safe CO₂ storage as well as high installation and running cost (de Coninck and Revi, 2018). Studies conducted to evaluate the costs and CO₂ removal/storage capacities of CCS and DAC show large variations in their findings, depending on the constraints assumed by the estimation models (Bui et al., 2018). The IPCC has analyzed several such studies and has settled with Fuss and colleagues' work (Fuss et al., 2018), which estimates CO₂ removal/storage capacity of 0.5–5 GtCO₂ per year and a cost ranging from 100 to 300 USD per ton of CO₂-equivalent removed (de Coninck and Revi, 2018). DAC ranks higher than CCS in terms of cost, due to the higher energy costs incurred through CO₂ removal from the dilute atmosphere as compared to a concentrated flue gas source (de Coninck and Revi, 2018).

With regards to BECCS, estimated potentials from the literature range from 0–50 GtCO₂ per year (de Coninck and Revi, 2018). Such a range suggests that BECCS can either provide no contribution in removing CO₂ from the atmosphere or single-handedly mitigate it to acceptable levels by 2050. With carbon

budgets rapidly on the decline, the latter scenario is plausible only with deep decarbonization (Gough et al., 2018). Fuss et al. has again incorporated restraints associated with the technique, such as the availability of safe CO₂ storage, to calculate a more practical estimated potential of 0.5–5 GtCO₂ per year (de Coninck and Revi, 2018; Haszeldine et al., 2018). Such a capacity range for BECCS merits further consideration in any comprehensive climate change mitigation policy framework. Additionally, high installation costs are characteristic of BECCS, which are estimated to be several hundred billion USD per year by 2050 at a rate of 3.3 GtCO₂ equivalent per year (Smith et al., 2016; de Coninck and Revi, 2018). Concerns regarding sustainability are not far-fetched as a similar carbon reduction potential can be reached by forestation techniques which are much less costly, albeit coming with their own environmental impact, *vide supra*.

Since the spectrum of CCS technologies is susceptible to cost-effectiveness in consequence to technological advances (Metz et al., 2005), significant investments by global entities have been made in the field of CCS as a means of meeting CO₂ mitigation targets. In their recent 2018 report, the European Union assessed the status of CCS technologies that had received nearly 1 billion euros of public tax funding in 2008 for commercial large scale deployment (Special Report, 2018). The report found the endeavor to be unsuccessful in commercializing CCS technologies due to low carbon prices set by regulations, wavering political interests of the EU states and the associated financial insecurities. Such a conclusion is not improbable as the opportunity to cultivate revenue with the geological storage of captured CO₂ is scarce, especially with CCS deployment being concurrent with increased energy consumption at point sources (Siirola, 2014). Whilst the levelized costs for coal and natural gas power plants have increased in the past decade due to market factors (Rubin et al., 2015), the deployment of CCS technologies has raised these costs by an additional 45–70% in the power generation sector (Irlam, 2017). It is, however, important to recognize that the long-term (end-of-century) cost savings associated with the deployment of CCS technologies in the context of CO₂ mitigation is in the US\$ billion–US\$ trillion range (Metz et al., 2005). As a result of the significant cost savings and the permanency of CO₂ storage achieved through the deployment of CCS, it has been established as a primary CDR technique (Page et al., 2019). Furthermore, it is widely understood that integration with some form of utilization is favorable for improving CCS economics (Zhu, 2019; Sandalow et al., 2017; Jones et al., 2017; Center for Climate and Energy Solutions, 2020).

Commercializing CO₂ removal through novel utilization can catalyze large scale implementation by creating a return on investment for financial input. An integrated process flow combining CO₂ removal and novel utilization in lieu of geological storage can improve CDR sustainability in terms of land use, cost, and environmental impact; whilst providing an economic value proposition to justify accelerated deployment. Novel CO₂ utilization has the potential to be market-viable and can be driven by free market factors, offering it an important advantage over conventional CCS methods in terms of potential traction and rate of adoption and growth. Accelerating CDR growth in the form of novel CO₂ utilization is particularly necessary as the collection of current CDR techniques with their associated advances are operating on only a few MtCO₂ per year removal scale (Bui et al., 2018; Malischek, 2020).

CURRENT STATUS OF NOVEL CO₂ UTILIZATION CHALLENGES

Since the 1920s, CO₂ has been used for a variety of industrial applications such as the carbonation of beverages, preservation of food items, and the enhanced recovery of oil (Kaliyan et al., 2007). Commercial grade CO₂ has generally been obtained as a by-product from other industrial processes such as the manufacture of ammonia gas and hydrogen fuel, as well as the burning of coke and coal (Kaliyan et al., 2007). As anthropogenic CO₂ levels continue to rise, the limited applications of CO₂ that is retrieved from industrial waste are currently insufficient as a significant component in the CO₂ utilization discourse. This further necessitates innovation in applications that employ CO₂, such as novel CO₂ utilization.

In the discussion regarding the utilization of captured CO₂, common applications that have been investigated since the 1970s are limited to pathways associated with enhanced oil/methane recovery and urea production (Global CCS Institute, 2011). However, since the late 2000s, institutions such as the Center for Climate and Energy Solutions (C2ES) (Bobeck et al., 2019), the Innovation for Cool Earth Forum (ICEF) (Sandalow et al., 2017), the U.S Department of Energy (U.S. Department of Energy, 2016) the Global CO₂ Initiative (CO₂ Sciences Inc., 2016) and the Global CCS Institute (2011) have published comprehensive reports on the practical pathways that can be undertaken for producing high quality products through novel CO₂ utilization. **Table 2** provides a non-exhaustive summary of

TABLE 2 | An abridged list of Novel CO₂ Utilization products with their associated status and potentials for CO₂ removal in gigatons. This list has been compiled from reports published by the Center for Climate and Energy Solutions (Bobeck et al., 2019), the Innovation for Cool Earth Forum (Sandalow et al., 2017), the U.S Department of Energy (U.S. Department of Energy, 2016) the Global CO₂ Initiative (Global CO₂ Initiative, CO₂ Sciences Inc, 2016) and the Global Carbon Capture and Storage Institute (Global CCS Institute, 2011).

Novel CO ₂ utilization pathway	Product	Status	Potential (GtCO ₂ removed per year by 2030)
Mineralization	Construction Materials (e.g., concrete and aggregates)	Demonstration to commercialization phase	0.3–3.6
Chemical	Polymers (e.g., polyurethane and polycarbonates)	R&D phase	0.0001–0.0002
Chemical	New Materials (e.g., carbon fiber and graphene)	R&D phase	Unknown
Chemical	Commodity Chemicals (e.g., methanol and carboxylic acids)	R&D phase	0.0001–0.0002

novel CO₂ utilization products with their respective phases of development and potentials for CO₂ removal (Gt).

Construction materials such as aggregates and concrete are at the forefront of novel CO₂ utilization with several commercial projects already underway (Zhu, 2019). Manufacturers that have been able to successfully design high quality products that incorporate a percentage of CO₂ gas are currently few, and those that have actively commercialized such products at a high Technology Readiness Level are further scarce. Due to the novelty of these technologies, knowledge about costs and CDR capacities are institution- and process-specific. As such, the collective scale of operation in terms of CO₂ capture and novel utilization is not yet known. In addition to the obscurity of CO₂ conversion pathways for creating value-added products, this lack of knowledge has prevented bodies like the IPCC from incorporating novel CO₂ utilization in their IAMs for climate mitigation (de Coninck and Revi, 2018). Whilst the demand of the current combination of novel CO₂ utilization technologies is enough to offset ~10% of anthropogenic CO₂ emissions (Zhang et al., 2020), several research avenues are being developed to further identify and create industrially relevant products that can replace conventional materials (Peters et al., 2011).

To date, novel CO₂ utilization technologies face a duality of challenges: firstly, with producing a net reduction of CO₂ emissions throughout their lifecycle; and secondly, providing good quality carbon commodities at an economically viable price point. To ensure that the process of novel CO₂ utilization remains carbon negative, it is pertinent to consider the amount of CO₂ removed from the atmosphere, the source of energy being utilized, and the CO₂ emissions incurred in the conversion and incorporation processes (de Coninck and Revi, 2018; Zimmermann et al., 2018; Müller et al., 2020). As is the case with all manufacturing processes, establishing cost-competitiveness for novel CO₂ utilization products in the first few years of operation can, and is proving to be challenging, particularly if cheaper alternatives already exist. For example, in an article by Bloomberg magazine, industry leaders have stated that customers are reluctant to purchase environmentally-friendly types of cement with low carbon footprint, as traditional cement offers a better price (Dezem, 2019). Additionally, software technologies provide a safer domain of investment, where the possibility of sunk costs are low, which further makes financiers reluctant to invest in comparatively high-risk hardware technologies. Should intermittent changes become necessary, as is often the case with innovation, redesigning codes in software can be a lot simpler than rebuilding hardware. Although novel CO₂ utilization technologies still require substantial capital for the installment of infrastructure relevant to CO₂ capture and associated conversion facilities, investment in this field is highly likely as governmental bodies are fiercely trying to meet their share of goals outlined by the Paris Agreement. Additionally, the US Department of Energy has compiled several reports discussing the financial feasibility and chemical processes of CCS with a keen interest in utilization as well (U.S. Department of Energy, 2016;

Mission Innovation, 2017). In September 2019, the Department announced an allocation of USD 110 million for the development and research of CCS technologies (US Department of Energy, 2019). The utilization of CO₂ is also included in this fund, which is currently limited to enhanced oil recovery (EOR).

Literature that has focused on assessing the viability of using captured CO₂ for chemical, plastic, or material production has found low TRL levels (Kätelhön et al., 2019) and low carbon prices (Smit et al., 2014) to be sources of hesitation in the employment of novel CO₂ utilization. In order for CO₂ to become a viable feedstock for chemical synthesis, carbon prices need to exceed the price of oil, which is the current major raw material for chemicals (Smit et al., 2014).

In addition to technical challenges, a lack of understanding and awareness regarding the concept of employing CO₂ emissions for a commodity market instills a fear of uncertainty and a greater reliance on fossil fuels, which perturbs public investments and political support (Bui et al., 2018). However, novel CO₂ utilization has the potential of becoming a multibillion dollar industry, in addition to reducing climate mitigation costs by 138% (Bui et al., 2018; U.S. Department of Energy, 2016). Cost savings are achieved by reduced expenditure on adaptation costs such as maintaining air quality and fresh water availability, as well as reduced economic loss due to damage to natural resources (IPCC, 2014). It is important to note that short-term (2030–2050) and long-term (2050–2100) mitigation costs are expected to increase by 44 and 37%, respectively, if mitigation measures employing CO₂ removal such as novel CO₂ utilization are delayed until 2030 (IPCC, 2014). Moreover, current energy intensive industrial processes that cannot be replaced with greener alternatives can be decarbonized *via* CO₂ capture and novel utilization, which furthers the importance of developing such technologies (Bui et al., 2018; U.S. Department of Energy, 2016).

In the production of manufactured goods through novel CO₂ utilization, several other unforeseen barriers to operations and upscaling may occur. For example, policy specifications by city or state bodies can cite limitations to the amount of novel CO₂ materials that can be incorporated in chemicals, construction materials, and fuels (Carey, 2017; Sandalow et al., 2017). It is also conceivable that the scales of CO₂ capture and novel CO₂ utilization may not coincide, resulting in either a lack of supply to keep operations running or a large requirement of geological storage for a surplus of captured CO₂. Companies that have successfully propelled their CO₂ utilization technologies in the commercialization stages, such as Carbon8, have sustained considerable years of R&D before enjoying a high TRL level (Carey, 2017). Such companies still face further commercialization challenges such as high CO₂ prices and strict standards preventing the incorporation of their materials (Carey, 2017). However, free market forces and directed policy incentives will enable these interfacial tensions to stabilize over time and reach market-driven, policy-nudged equilibriums similar to how the solar industry gained a foothold under Obama's green building initiative in 2008–2010.

POTENTIAL FUTURE PATHWAYS

In order to assess the plausible pathways that the novel CO₂ utilization market may take, it is important to extrapolate lessons from other hardware-heavy technology industries that have scaled successfully across the world, and to analyze their historical genesis, evolution, and development cycles. This section studies the development of two different successful technology industries: solar and automobile. These particular industries were chosen for analysis as their growth and deployment has occurred under vastly different circumstances and scales, leveraging different resources and trends to sustain accelerated growth. Moving forward, novel CO₂ utilization at an industrial level may follow either, or a combination of these paths to commercialization and upscale.

THE SOLAR INDUSTRY

The roots of the solar industry can be traced back to the discovery of the photovoltaic effect in 1839 (Harvey et al., 2017) which illustrated the production of an electrical current in a material upon its exposure to sunlight (Bube and Fahrenbruch, 1981). The following four decades were spent verifying and studying this discovery before a device capable of converting solar energy into electricity at a rate of 1% efficiency was invented in 1882 (Harvey et al., 2017; The History of Solar, 2019). The next 70 years saw periods of small improvements, dictated by a series of solar cell patents, experimentation with photoelectric materials, and academic studies (Harvey et al., 2017; The History of Solar, 2019). The industry took a leap when a fully functional solar cell was constructed by Bell Laboratories in 1954 which was capable of powering electrical equipment while operating at a conversion efficiency of 6% (Harvey et al., 2017; The History of Solar, 2019; Perlin, 2004). This device was well-funded and created in an attempt to find an alternate source of power for the company's telephone system, as their conventional batteries were inefficient in tropical climates (Perlin, 2004). Interestingly, from concept to fabrication, the Bell solar cell entertained a mere 2 years of development, as compared to the preceding 70 years spotted with instances of advancements for solar cells (Perlin, 2004). In the case of novel CO₂ utilization, growth has already begun to accelerate in a likewise manner, as the urgency of climate mitigation has pushed several institutions and investors, like the U.S Department of Energy, to seek a range of possible solutions.

With the invention of Bell Laboratories' solar cell, licensing and further efforts to increase the efficiency of solar cells continued throughout the 50–60s (The History of Solar, 2019). Bell Laboratories was joined by the RCA Corporation and Hoffman Electric in simultaneous experimentation with different materials and electronic junctions to increase the solar-to-current conversion rate in increments until a 14% efficiency rate was achieved by 1960 (The History of Solar, 2019). This increase in efficiency was incentivized by inter-company competition and power supply requirements for space exploration shuttles and satellites during the latter decade when space programs were fueled by government

support (The History of Solar, 2019; Perlin, 2004). Similarly, today in the novel CO₂ utilization market, competition is increasing as numerous start-ups, especially under the Carbon X-PRIZE competition, are developing their pathways for utilization toward commercialization. It is important to note that the demand for CO₂ utilization stems from a mix of private and government sectors, as opposed to the solely government-led projects in the case of solar cells.

In the 1970s, the solar industry was fueled by the United States' government in an effort to relieve the energy crisis (Pinner and Rogers, 2015). This agenda prompted big corporations as well as governmental branches to provide regulatory support and investments for the development of solar energy. In 1972, Exxon Corporation funded research into the production of a solar cell that could reduce cost from 100 to 20 USD/Watt (The History of Solar, 2019). By the late 70s, the United States' government dedicated entire facilities for the improvement of solar energy, which was followed by the deployment of several photovoltaic systems for public use (The History of Solar, 2019). In 1978, a 3.5 kW photovoltaic system was built to power a small village in Arizona and by 1982, a 1 MW scale power station was built in California (The History of Solar, 2019). In the same year, the US Department of Energy built a 10 MW scale solar demonstration facility with the help of industrial partners (The History of Solar, 2019). Global use of solar cells for electricity generation continued to increase on the MW scale and by 1993, a photovoltaic system which was grid-supported was built in California (The History of Solar, 2019). By the year 2000, photovoltaics had reached a capacity of 0.3 GW and were ready for larger scale deployment (Pinner and Rogers, 2015; Harvey et al., 2017).

The discovery of the photovoltaic effect was followed by two centuries worth of investigations and improvements before any scale of commercialization was reached. In order to establish the novel CO₂ utilization industry as a significant force in the climate mitigation dialogue, it is necessary to avoid the hiatuses in terms of efficiency and capacity that the solar industry faced. The scale of development achieved in the two centuries must be condensed in mere decades for the CO₂ commodity market to cause a sizable dent in emissions by 2050 (IPCC, 2014). The involvement of the US Department of Energy assisted in the demonstration and popularization of the solar industry, which parallels and shows promise for the development of the novel CO₂ utilization market as well. Regulatory support by the United States government has administered improvements to the 45Q policy, which provides a tax credit for every metric ton of CO₂ captured or utilized in enhanced oil recovery (Bobeck et al., 2019; US Department of Energy, 2019).

In addition to policy regulation, the United States government offered subsidies to manufacturers of solar cells and users alike, in order to create a demand for solar power. Homeowners were given \$15,000–\$20,000 to alleviate the one-time installation costs alongside feed-in-tariffs that provided a guaranteed price per kW of solar power for energy providers (Pinner and Rogers, 2015). Despite the collapse of the solar energy market in the early 2000s, state and government subsidies allowed for it to rise once again. By 2014, the market for solar energy was fostered enough to create solar photovoltaic panels with a capacity of 45 GW (Pinner and Rogers, 2015).

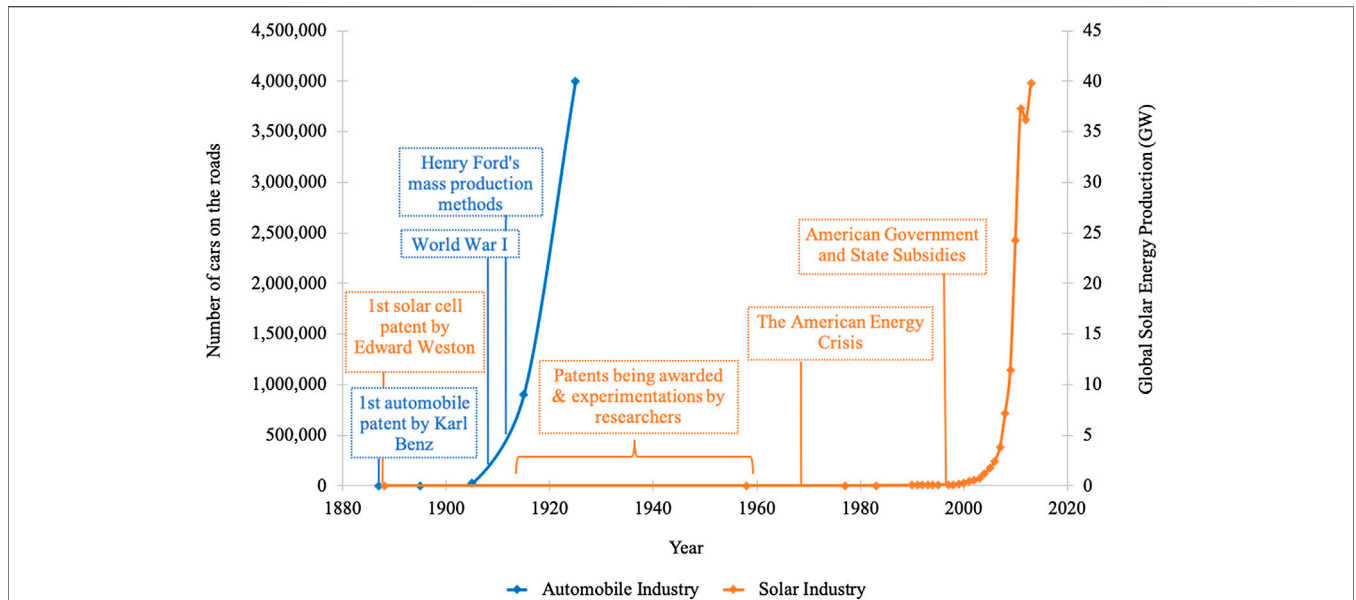

FIGURE 1 | A comparison of the trajectories of the American solar and automobile industries with respect to output in terms of the number of cars present on roads for the automobile industry and the amount of energy produced (GW) for the solar industry.

From the case of the solar industry, it can be determined that in order to increase the frequency of large-scale projects, escape market failures, and ensure that the CO₂ commodity market stays competitive, investments, subsidies, and grants are needed to be instituted by governing bodies. Moreover, current policies that provide incentive for CO₂ utilization such as the 45Q Tax Credit policy should lower the bar of eligibility from 25,000 mt (0.025 Mt) of CO₂ utilized to enable small-scale projects (Smith et al., 2016). Additionally, business-consumer

relationships need to be created for the CO₂ commodity market to be widely accepted and for fears regarding fossil fuel reliance to be discredited.

Figure 1 shows the growth curves of the automobile and solar industries. Although developments in both solar and automobile industries escalated exponentially, their respective impacts on the energy and transportation sectors have been vastly different. Whilst the number of automobiles produced quickly superseded the production of horse-carriages and wagons

FIGURE 2 | A comparison of the American production statistics of automobiles and horse-carriages/wagons. Values of automobile production obtained from (Griffin, 1925). Values of horse-carriages/wagon production units obtained from the US. Department of Commerce archives (Steuart and Hawes, 1918).

(Figure 2) (Griffin, 1925; Steuart and Hawes, 1918), the contribution to power generation from solar energy has not yet reached the level of fossil fuel generated power (Figure 3) (Smil, 2019; Our World in Data, 2018; bp, 2019). Additionally, literature shows that large scale adoption and diffusion of new technologies not only require cost-competitiveness but an actual increase in profit (Hall, 2016). In the context of CDR technologies, this means that simply being environmentally friendly is not a realistic economically perceived criteria for large scale usage (Popp, 2010). The results of following this scenario are currently observed in the case of traditional CCS technologies that incur an additional cost for implementation without any real benefit to the industry, *vide supra* (Bui et al., 2018).

THE AUTOMOBILE INDUSTRY

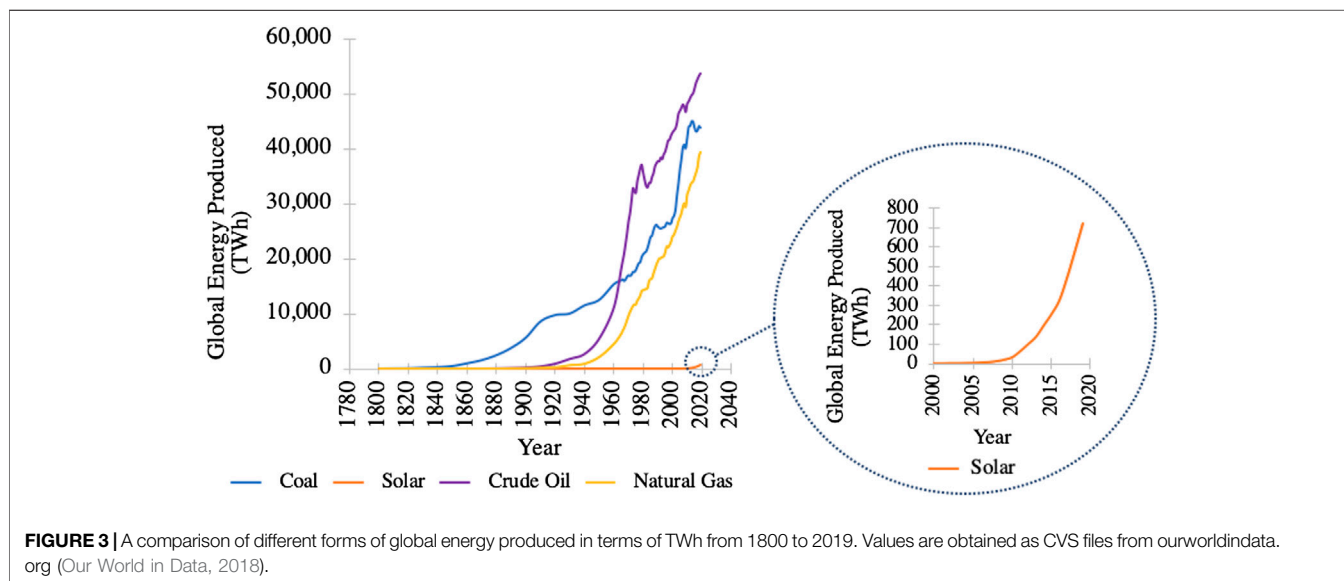

Another industry with a successful commercialization history is the automobile industry. The globally ubiquitous automobile underwent several important developmental phases since its inception which are discussed herein. Given that automobiles are a standard commodity in most North American households, it may be easy to forget that this situation did not come to be overnight. It was not until the early 1900s that automobiles surpassed the use of horse-drawn vehicles, and several factors spanning over five decades from the late 1800s to the early 1900s were instrumental in facilitating this irreversible change (Cromer et al., 2018).

There are differing opinions as to when and by whom the first automobile was invented, as several attempts were made in the late 18th century to replace horse-drawn carriages. Notably, in the 1760s, after the advent of the steam engine, Frenchman Nicolas-Joseph Cugnot (Cromer et al., 2018) built a steam-powered artillery vehicle which could also be used for transportation purposes (autoTRADER.ca, 2019). The design features of this

vehicle caused an uneven distribution of weight and deemed its usage impractical. However, the development of automobiles was not perturbed and in the following decades several more attempts were made to create practical, self-propelled, steam-powered vehicles.

An important leap for automobiles occurred in 1871 when Dr. John W. Carhart invented a steam-powered carriage able to feasibly tread on the already present wagon roads of Wisconsin (McBride, 1999). The resulting spark of interest was exemplified in state-wide competitions for building practical alternatives to animal-based vehicles. From there onwards, the most noteworthy milestone occurred in 1886: the patenting of The Benz Motorwagen by Karl Benz (Benz, 1886; Sovacool, 2009). The novelty of this automobile arose from the petroleum-based internal combustion engine used as the propellant of the vehicle (Cromer et al., 2018). From concept to fabrication, Benz dedicated two decades in order to counter the monetary challenges that had plagued the progress of his automobile (Seltzer, 1928). His project came to fruition when the automobile experiment was financed by his wife's dowry and the investment of two private Mannheim investors, who were well aware of Benz's talent and expertise (Dickmann et al., 2014). In comparison, a similar magnitude milestone from the solar industry, the Bell solar cell, took just 2 years to be constructed, as the project was funded by a well-established company.

Benz's project was popularized once Bertha Benz demonstrated the practical use of this automobile for long-distance travel, which entered the realm of commercial production when Benz demonstrated it during the Paris Exhibition of 1887. Simultaneous to the invention of the Benz Motorwagen was the production of the gasoline-driven automobile by Gottlieb Daimler (Cromer et al., 2018). Due to the efficiency of Daimler's engine, this vehicle won the first Paris-Rouen international automobile race in 1894, and secured a sizable price which was further used to develop the vehicle according to the increasing demand of higher horsepower

(Seltzer, 1928). By 1895, 300 motor vehicles had been sold on the market (Griffin, 1925). These initial sales were made to wealthy folk to be exclusively used for recreational activities such as touring and cross-country racing (American Automobile Production, 1928). Since Benz and Daimler's internal combustion engine-based vehicles met the elite community's requirement of long-distance travel and enjoyed the advantage of a short engine lag time, their sales flourished and a "car culture" was born (American Automobile Production, 1928). In contrast, electric vehicles remained operational for a short period of time before the batteries required charging, making them unusable for long-distance travel, while steam-engine based vehicles suffered a long and inconvenient delay for steam formation before people could embark on a journey (American Automobile Production, 1928). It is important to note that no government support is evident in the first 30 years of automobile development, which had been driven entirely by private, independently rich investors, and sold as a luxury product. Additionally, advancements made while serving this high margin clientele steadily allowed for the higher scale of production, economies of scale, and significant cost reductions that ultimately made cars ubiquitous, as was with the case of many 20th Century innovations (Hall, 2016).

By 1905, the yearly production of automobiles approximated 25,000 in numbers (Griffin, 1925). Monumental to this advancement was the dissatisfaction incurred from the waste generated on roads from the use of horses as a means of transportation (Thompson, 2019). As city populations grew and industrialization progressed, the environmental dilemma of disease-ridden horse dung overgrew the advantage of the self-subsisting and economical animal. The automobile was deemed a greener alternative by urban developers and was heavily promoted by publications such as "The Horseless Age" as a definitive solution to the road sanitation (Nikiforuk, 2013). To enhance citizens' comprehension of automobile benefits, the unit of horsepower was employed to define the working power of automobiles (Thompson, 2019). Further marketing strategies by motorists, car manufacturers and wealthy car owners helped to ultimately relieve some of the concerns that came with automobile use, such as safety. The appearance of asphalt paved roads in the 1870s granted easy assimilation for the use of petrol-fueled automobiles (Thompson, 2019). In an effort to improve city sanitation in the late 19th Century, engineers re-designed roads to accommodate sewage systems and asphalt became the preferred material to rebuild roads as it allowed for a more comfortable travel experience (Thompson, 2019). In the early 1900s, automobiles in the United States and Europe were handmade by several small companies that went out of business just as easily as they first started (Seltzer, 1928). This was attributed to high competition and the inability to reach economies of scale. With the advent of assembly lines and synchronized manufacturing in the 1910s, mass production became prevalent thanks to the efforts of Henry Ford and Ransom E. Olds (American Automobile Production, 1928). In 1915, 900,000 automobiles were produced and sold, in contrast to the 300 cars present in the market just under 20 years ago in 1895 (Griffin, 1925). This stage was characterized by the early industrialists as the end of the demonstration period in

automobile development, as this technology was no longer perceived as novel. At the onset of World War 1, the advantage of mass-produced internal combustion automobiles was established, which were used for long-range transportation and military activities. By 1925, ~4 million automobiles were present on roads and the industry entered into the phase of global expansion (Griffin, 1925).

Through the example of the automobile industry, it is understood that initial attempts at developing novel CO₂ utilization technologies may serve a less commoditized, higher margin market before turning to commodities. Additionally, leveraging niche product lines that buy the technology time to iterate and improve its economic metrics and support infrastructure over time may be required. Trial and error in the industry is a natural course to upscaling with demonstration environments such as the Paris-Rouen competition in the case of automobiles, and the Carbon X-PRIZE competition in the case of novel CO₂ utilization, allowing for increased investments. With the solar industry, the initial solar cells were a company venture which transitioned into a country-wide necessity in later years. Both turning points were heavily financed by interested parties, whereas automobiles being personal ventures did not receive governmental or corporate funding until much later into their lifecycle. Currently, novel CO₂ utilization resembles solar industry, with multiple organizations and governments interested in its deployment (Strefler et al., 2018). The demand of automobiles grew rapidly in a short amount of time as this invention surpassed the performance ability of traditional transportation for commercial, personal, and military uses. Solar cells in contrast have not seen a complete displacement of traditional sources of energy. Moving forward, the ideal scenario for novel CO₂ utilization is to design products and materials that out-perform traditional materials such as cements, plastics, and biofuels. **Figure 1** shows similar exponential growths for both industries considered herein, with the solar energy curve being shifted almost a century forward.

RECOMMENDATIONS AND CONCLUSION

The field of CDR operates in a nexus of industrial energy systems and consumer behavior. Conventional fossil fuel energy sources and the use of automobiles contribute to a significant proportion of CO₂ emissions globally (Hall, 2016), and technologies in both these sectors offer important insights into challenges and opportunities in deploying novel CO₂ utilization at a meaningful scale to reduce carbon emissions.

Whilst the solar industry received government support at virtually all TRL levels, the automobile industry, due to its inherently superior value proposition relative to the status quo, relied solely on small, private investments in its first 30 years of development. Both technologies, however, consistently improved their offerings through iterative and breakthrough advances.

Combining an effective market value proposition with targeted policy incentives, whilst facilitating the development and optimal operation of fundamental and empirical research

and development in the field of novel CO₂ utilization, is critical to enabling and accelerating the global deployment of this suite of CDR technology.

Based on the development trajectories of two commercially relevant and successfully scaled industries, the following factors are recommended for consideration in order to accelerate the development of novel CO₂ utilization technologies:

- (1) A principles-driven framework to address the systemic challenges associated with hardware-heavy technology sectors, particularly novel CO₂ utilization technologies, needs to be established and adhered to. The principles could include:
 - a. Technological analysis on scope, impact potential, scalability challenges, and current state of supplementary technologies required for scaled deployment.
 - b. Economic analysis considering commercial viability, status of target markets, short- and long-term trends, and business models (evaluated differently for Business-to-Business and Business-to-Consumer ventures).
 - c. A standardized CO₂ utilization-wide definition of TRL (Technology Readiness Level) and IRL (Investment Readiness Level) adjudicated by an independent board of experts to ensure consistent evaluation of technologies across the industry.
 - d. Transparent feedback on all pathways considered to ensure an efficient dissemination of technology and market-related information.
- (2) A fundamentals-driven exercise to identify and investigate potential pathways that can meaningfully reduce global CO₂ emissions using realistic technical and economic assumptions must be conceived and deployed by the stakeholders and decision makers in the field.
- (3) An organized access to public and private capital for the scale-up and commercial delivery of pertinent technologies need to be established. This can be achieved by:
 - a. Development of clear pathways for funding at various TRL and IRL levels.
 - b. Commissioning of a Carbon Reduction program that follows the setup of Advanced Research Projects Agency–Energy (ARPA-E), focused on utilizing start-ups to combine fundamental research with industry partners.
 - c. Regular technical and investment workshops to ensure consistent communication between academia, entrepreneurs, public and private investment entities.
 - d. Formulation of 1- and 5-year plans to establish key performance metrics associated with research, development, and commercialization aspects of the industry.
- (4) Policy incentives provided by individual governments need to be revised for accelerating the deployment of novel CO₂ utilization technologies at a holistic global level.

- a. The Canadian government should provide a comprehensive guideline on the eligibility criteria for its Carbon Capture Tax Credit (CCTC) program to incentivize the standardization of CO₂ utilization technologies. A framework for grant eligibility should be established with funding options covering all aspects of the CO₂ utilization process from R&D to operations and commercialization.
- b. The US Department of Energy should extend and specify tax benefits regarding the 45Q policy, while reducing the threshold for projects to be eligible, thereby enabling synthesis of vast processes and products pertaining to CO₂ utilization technologies.
- c. The European Green Deal should include investment policies and initiatives regarding CO₂ utilization technologies to catalyze the adoption of CCS and improve its commercial viability.

To achieve carbon emission reductions of scale, significant behavior change is required from customers to facilitate successful industrial deployment of novel CO₂ utilization technologies. Importantly, a transparent and standardized methodology on all proposed CDR pathways needs to be developed and shared across the system to create a motive for behavioral change and adoption.

To effectively address these challenges, the deployment capacity, economic feasibility, and the permanence of carbon fixation in the new products and materials are fundamentally important considerations for any CO₂ utilization technology and associated business. Tackling the collection and the deconvolution of this information requires scientific and engineering innovation as well as cross-disciplinary collaborations to replace traditional methods. As with many other hardware technologies, the concert of public and private support of vetted technology projects is vital for scale up and commercialization of novel CO₂ utilization technologies, in order to overcome the hampering inertia of high cost, low production quality and small-scale.

Due diligence is needed on part of scientific experts and policy makers in order to substantiate claims to avoid unjust romanticizing of the fruits of the CO₂ utilization market. CDR is a portfolio of techniques and should be treated as such. Enhanced oil recovery and BECCS are but threads in the grand fabric of CDR, and not one technology or technique is the crux of climate mitigation. As such, enabling novel CO₂ utilization technologies to mitigate CO₂ emission trends is critical if COP21 commitments are to be met.

AUTHOR CONTRIBUTIONS

YW is the primary author of the paper, she compiled the review materials and wrote the manuscript. VK and PZ are co-authors of the paper, they both contributed to the editing of the manuscript and content organization. AS is the primary investigator for the manuscript, he provided the direction for the review and aided in the editing process.

ACKNOWLEDGMENTS

The authors would like to express our gratitude to Alberta Innovates, and the University of Calgary nanotechnology group (UofC nanoGroup), respectively, for funding and organizing the 2019 Calgary nanoNexus networking event which ultimately enabled an industry-academia collaboration leading to the completion of this manuscript.
