The technology advancement and cost decline of renewable and sustainable energy increase the penetration of distributed energy resources (DERs) in distribution systems. Transactive energy helps balance the local generation and demand. Peer-to-peer (P2P) energy trading is a promising business model for transactive energy. Such a market scheme can increase the revenue of DER owners and reduce the waste of renewable energy. This article proposes an equilibrium model of a P2P transactive energy market. Every participant seeks the maximum personal interest, with the options of importing or providing energy from/to any other peer across different buses of the distribution network. The market equilibrium condition is obtained by combining the Karush–Kuhn–Tucker conditions of all problems of individual participants together. The energy transaction price is endogenously determined from the market equilibrium condition, which is cast as a mixed-integer linear program and solved by a commercial solver. The transactive energy flow is further embedded in the optimal power flow problem to ensure operating constraints of the distribution network. We propose a remedy to recover a near optimal solution when the second-order cone relaxation is inexact. Finally, a case study demonstrates that the proposed P2P market benefits all participants.

Keywords: distribution network, market equilibrium, optimal power flow, peer-to-peer trading, transactive energy

INTRODUCTION

With the development of modern society and economy, the energy consumption is continuously increasing. However, due to the depletion of nonrenewable energy and the greenhouse gas emission from burning fossil-fuel energy, it is imperative to develop renewable and sustainable energy (Liu et al., 2020). The technology advancement and cost decline contribute to the high penetration of distributed energy resources (DERs), such as solar photovoltaics, wind turbine, and energy storage devices, in the power system (Hou et al., 2021). In such circumstances, there could be multiple generation sources that are volatile and owned by profit-driven entities. The Feed-in Tariff (FiT) scheme has been implemented as an effective tool to encourage DERs investment and owners' participation in energy trading (Pyrgou et al., 2016). In the FiT scheme, DER owners can sell their excessive energy to main grid at a designed price. But the FiT scheme has been criticized for lacking competition (Butler and Neuhoff, 2008) and offering participants limited benefits (Tushar et al., 2015).

The transactive energy system is proposed to manage the energy generation and consumption and facilitate energy trading in the power system. The transactive energy scheme helps balance the local renewable energy generation and demand in the timeframe of real-time within a distribution network (Abrishambaf et al., 2019).

With the advancement of Information and Communication Technology (ICT), peer-to-peer (P2P) energy trading has been designed and expected to be a promising business model for the transactive energy scheme in future power systems (Abdella and Shuaib, 2018). P2P trading is composed of energy buyers and sellers, power system operators, and P2P service servers. A peer in the P2P market can sell surplus energy to local peers and can choose to act as an energy buyer or seller based on personal preferences and needs (Giotitsas et al., 2015). All peers can exchange energy with each other directly, without the involvement of utility companies. The implement of P2P energy trading enables all peers to engage in energy trading, thus creating a competitive energy market. Both the energy buyer and the seller can benefit from P2P transaction because they can utilize excessive renewable energy and reach a mutually satisfactory price and quantity (Mengelkamp et al., 2018). The P2P transactive market can also balance local energy supply and demand, thus reducing energy transmission losses. Furthermore, it can improve the power system reliability and reduce infrastructure investment (Shrestha et al., 2019).

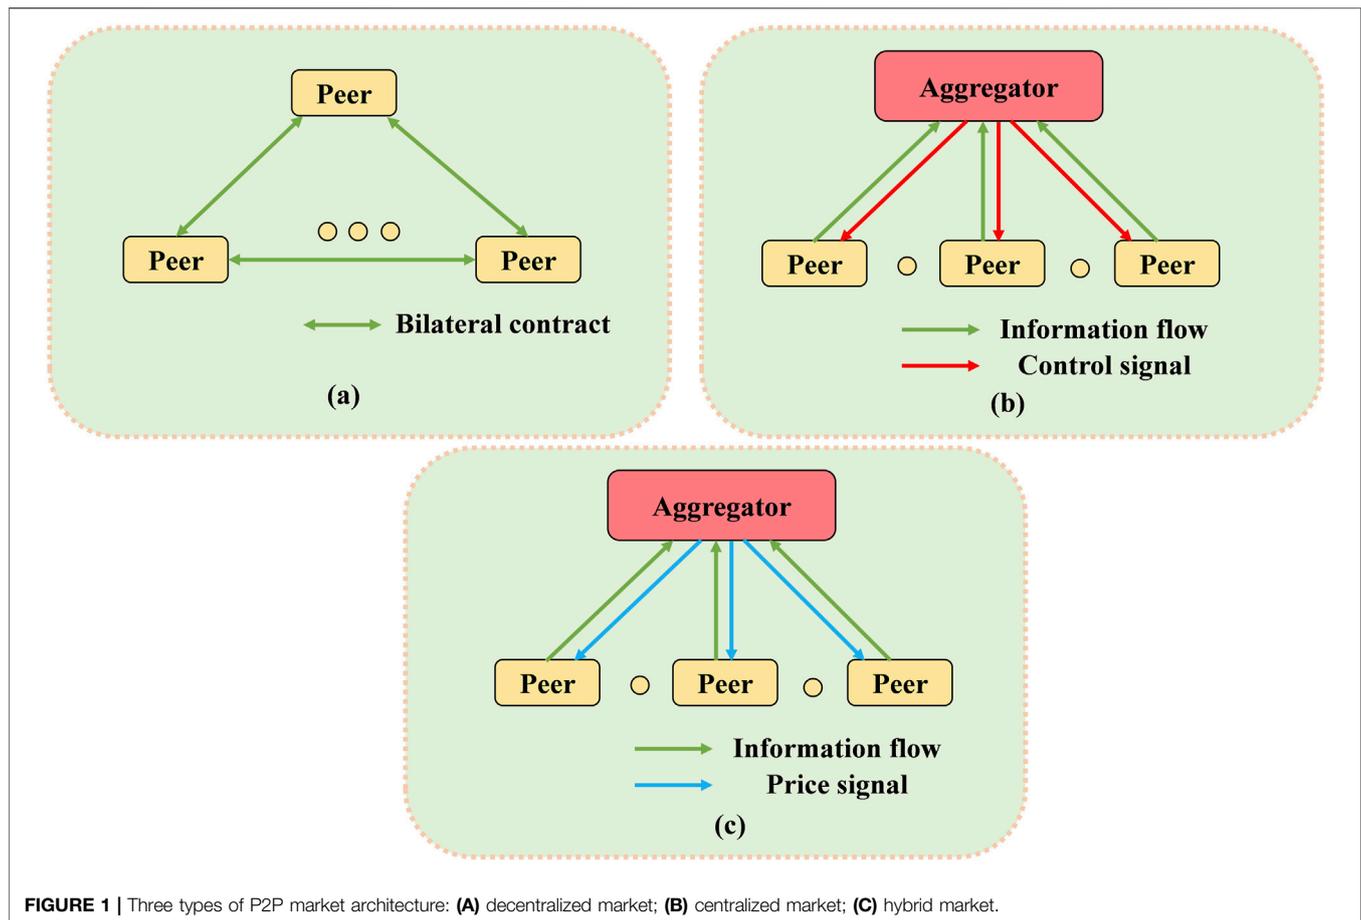

Recently, P2P energy trading has attracted great attention as never before and an increasing number of researches have been conducted to facilitate the P2P trading mechanism. The state-of-the-art of P2P energy trading is presented as follows.

There are many articles summarizing the design and architecture of the P2P energy trading market. Tushar et al. (2020a) provided a detailed overview in the P2P energy trading field and discussed the solution techniques implemented in the P2P market. The key elements in the P2P market can be divided into virtual layer and physical layer. The virtual layer has the transaction data flow and the market mechanism while the physical layer consists of the power grid and communication infrastructure to guarantee that the physical energy transaction is carried out successfully. Zhang et al. (2018) proposed a four-layer system architecture in the P2P market, providing evaluation criteria to identify related technologies, facilities, and designs. The proposed architecture has three dimensions. The first dimension consists of business layer, control layer, ICT layer, and physical power grid layer, which form the basic framework in the P2P market. The second and third dimensions are classified according to the size of participants and energy trading process, respectively. Sousa et al. (2019) categorized the community-based P2P structure into full market, community-based market, and hybrid market according to the degree of connection and communication. In the full market, the peers can directly trade with each other without centralized coordination. By contrast, the community-based market requires a community manager to arrange the energy transactions within the community or between communities. The hybrid market is the combination of the above two market structures. Long et al. (2018a) categorized the P2P energy trading based on the existence of an intermedia. Without an intermedia, prosumers can directly control their DERs and a P2P market coordinator is needed to collect participants' information and provide price signal. With an intermedia, a third party can manage prosumers' energy and act as a market coordinator. In summary, the previously proposed P2P market architecture can be mainly classified as three types

based on the degree of decentralization: decentralized market, centralized market, and hybrid market, as shown in **Figure 1**.

1) *Decentralized market*: In a decentralized P2P energy market, peers can negotiate and trade with each other directly without the intermediary. The market participants can decide their transaction amount and price to maximize their personal interest and satisfy own preferences. Sorin et al. (2018) proposed a decentralized P2P market design based on multi-bilateral economic dispatch (MBED). The authors described a relaxed consensus + innovation (RCI) approach to solve the MBED. Such a market can cater to consumers' product differentiation preference and maximize society surplus. Morstyn et al. (2019) established a bilateral contract network for scalable P2P energy trading for real-time and forward market. The utility-maximizing preferences of agents satisfy full substitutability, which guarantees a stable result in the distributed price-adjustment process. Guerrero et al. (2019) designed a decentralized P2P scheme with a self-interested agent. The pricing mechanism builds on continuous double auction (CDA). This scheme is also the first decentralized P2P architecture considering distribution network constraints. Alvaro-Hermana et al. (2016) presented a P2P energy trading application scene in electric vehicles (EV) with the objective of minimizing EV users' energy expense. The implementation of P2P trading benefits users involved in the market and decreases charging impact on grid. Tushar et al. (2020b) proposed a P2P trading design based on coalition formation game. In such a prosumer-centric market, a prosumer can decide to join the P2P market or not by evaluating the P2P market's attractiveness. Prosumers can also choose whom to cooperate or not to achieve more benefit.

2) *Centralized market*: In a centralized market, an aggregator communicates with peers and manages the operation of DERs. The aggregator collects information from participants and makes proper control decisions of devices to reach a common target, for example, maximizing financial benefit or achieving an environmentally friendly goal. Kang et al. (2017) implemented localized P2P energy trading among plug-in hybrid electric vehicles (PHEVs). Local aggregators communicate with PHEVs, acquire their charging and discharging demand, and allocate energy with a goal of maximizing social welfare. Alam et al. (2017) proposed a P2P energy trading model with a Pareto optimality method. The proposed model requires the centralized manager to solve a multiobjective optimization problem, including microgrid energy cost minimization and individual cost optimization, and finally obtain Pareto optimality results, eliminating unfair cost distribution. Long et al. (2018b) developed a two-stage aggregated control method in P2P energy sharing where an energy sharing aggregator controls DERs to reduce total energy cost. An adjusted supply and demand ratio pricing mechanism is proposed to benefit all participants. Nguyen et al. (2018) proposed a centralized P2P trading mechanism in a local community with rooftop PV and battery. The objective of the aggregator is to minimize the total energy cost and the problem is formulated as a mixed integer linear programming (MILP). Long et al. (2017) introduced a centralized P2P energy trading to maximize the local energy balance. A linear programming is implemented to solve the market.

3) *Hybrid market*: Hybrid market is the combination of decentralized and centralized markets, in which a peer can decide to switch from the conventional energy market to the P2P energy market with the price signal from the aggregator. On one hand, the hybrid market requires an aggregator to manage and supervise transaction activities compared with the decentralized market. On the other hand, peers can control their devices, achieve self-interest, and protect personal privacy in comparison with the centralized market. Long et al. (2018a) presented three representative P2P market designs with different pricing mechanisms. They are, respectively, bill sharing, mid-market rate, and auction-based pricing strategy. Qi et al. (2019) constructed a P2P transaction model, with the aim of maximizing prosumers' benefit. The proposed model considers the impact of distribution network constraint on P2P transaction. Zhang et al. (2016) devised a bidding platform "Elecbay" based on the noncooperative game theory, in which all peers make their decision independently. The agents with flexibility of demand in the platform can mathematically lead to Nash equilibrium. Morstyn and McCulloch (2019) proposed a P2P market based on multiclass energy management, in which a distributed price-directed optimization mechanism is constructed to respect prosumer preferences and minimize external cost.

Game theory approaches, optimization methods, and auction-based approaches are widely used in designing P2P energy trading. Game theory is used in a competitive circumstance in which a player's decision and action will affect other players' outcomes and vice versa. Game theory approaches are grouped into two parts: noncooperative and cooperative game theory (Tushar et al., 2018). The author summarized several P2P energy management domains adopting game theory approached, including electric vehicle, DERs, energy storage, and energy service. Optimization methods are widely used in the P2P scheme. In Nguyen et al. (2018), an agent with rooftop PV and battery participates in P2P energy trading and proposes a centralized P2P trading mechanism in a local community with rooftop PV and battery and a mixed integer linear programming is proposed to minimize the total energy cost. Morstyn and McCulloch (2019) used the distributed convex optimization method alternating direction method of multipliers (ADMM) to solve the multiclass energy management problem. Auction-based approaches can be applied to markets with multiple energy buyers and sellers. Continuous double auction is used to match energy sellers and buyers and bidding strategies is proposed to facilitate agent's bid and ask (Guerrero et al., 2019). An iterative double auction algorithm is proposed based

on consortium blockchain to disclose hidden information about electric vehicles (Kang et al., 2017).

However, there are still some research gaps in the existing research works. Many studies did not concentrate on individual P2P market participant's interest, and such a market mechanism might damage personal interest. Many pricing designs in the P2P energy sharing market did not reflect the true value of transactive energy resources in different supply–demand scenarios and could not guarantee every participant's benefit from the market. P2P transaction should be conducted *via* physical distribution network, whereas the operating constraints are rarely taken into consideration.

In this article, we study transactive energy in a P2P market with participants at different buses of a distribution network. The main contributions are twofold.

- 1) We propose an equilibrium model of a P2P transactive market. Every participant is rational and pursues profit maximum, with the options of importing or providing energy from/to any other peer across different buses of the distribution network. The market equilibrium condition is obtained by combining the Karush–Kuhn–Tucker (KKT) conditions of all problems of individual participants together. Specifically, the price is endogenously determined from the market equilibrium condition, rather than bid by the providers, which is different from existing works and better reflects the value of resources in accordance with the supply–demand relation. The market equilibrium condition is further cast as a mixed-integer linear program and solved by a commercial solver.
- 2) We formulate the distribution optimal power flow (OPF) problem considering the transactive energy flow at the market equilibrium. To solve the nonlinear OPF problem, the second-order cone relaxation is performed. If the convex relaxation is inexact, a feasible recovery procedure is suggested to recover a near-optimal solution. The procedure entails solving second-order cone programs and is thus efficient. Such a framework offers a new paradigm to study power system operation with P2P transactive energy.

The remainder of this article is organized as follows. The P2P transaction scheme, the mathematical model of the P2P market, and the market equilibrium condition are presented in *P2P Transactive Scheme and the Market Equilibrium*. The distribution OPF problem considering the transactive energy flow of the P2P market and the solution technique are given in *Optimal Power Flow With Transactive Energy*. Case studies are reported in *Case Study*. Finally, *Conclusion* concludes the article.

P2P TRANSACTIVE SCHEME AND THE MARKET EQUILIBRIUM

In this section, a P2P transactive energy scheme is proposed. The problems of energy sellers and buyers are then presented. At last, the market equilibrium condition is given and cast as an MILP.

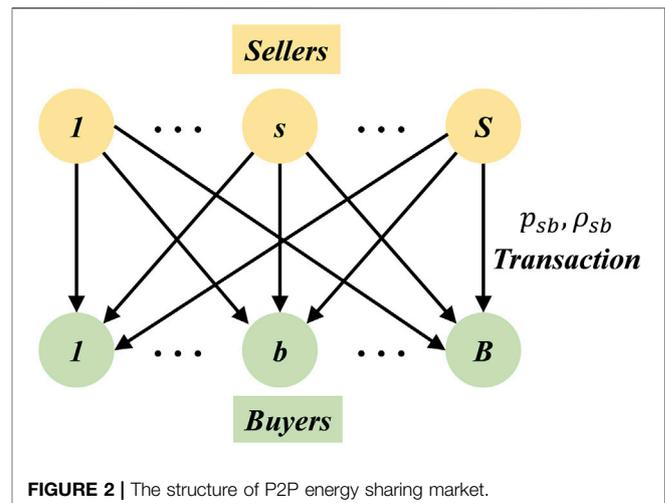

FIGURE 2 | The structure of P2P energy sharing market.

Problem Description

The transaction structure of the P2P energy-sharing market proposed in this article is shown in **Figure 2**. In this article, a peer who has excessive energy and shares energy with other people is identified as a typical energy seller s . Similarly, a peer with deficit energy is recorded as a typical energy buyer b . In a time period, there are total S energy sellers and B energy buyers joining in the P2P market. The solid arrow connecting seller s and buyer b in **Figure 2** represents P2P transaction between them. The variables p_{sb} and ρ_{sb} present the transaction energy amount and transaction price, respectively. In such a market, the following assumptions are made without loss of generality:

- 1) The infrastructure has been installed to operate P2P sharing scheme.
- 2) Associated stakeholders in the P2P market are rational and maximize their own interest. A contract with p_{sb} and ρ_{sb} is reached to ensure the transaction. The transaction is expected to be carried out hourly.
- 3) Energy sellers can choose to sell their surplus energy to the main grid in the FiT scheme or trade in the P2P market. Similarly, buyers can also purchase energy from the grid or the P2P market, with the hope to minimize their costs. A seller or buyer can sell or buy energy at a higher or lower price in the P2P market compared with traditional power utility. Otherwise, people will have no incentive to participate in P2P sharing.
- 4) The P2P market is operated by an aggregator. It collects supply and demand information from participants and clears the market. Then, it sends transaction results to the distribution grid.
- 5) All players are self-interested and they will not form an alliance. Besides, we assume all players tell their true supply and demand information to the aggregator.

Mathematic Formulation

The models of sellers, buyers, and total P2P market are presented in the following subsections.

Seller's Problem

A rational energy seller s seeks contract amount p_{sb} with energy buyer b to reach maximum profit. The optimal problem of seller s is

$$\max : \sum_{b \in B} \rho_{sb} p_{sb} + \lambda^{\text{sell}} \left(P_s - \sum_{b \in B} p_{sb} \right) - \lambda^{\text{cost}} \sum_{b \in B} p_{sb} \quad (1)$$

$$\text{s.t.} : \sum_{b \in B} p_{sb} \leq P_s : v_s \quad (2)$$

$$p_{sb} \geq 0 : \omega_{sb}, \forall b \in B \quad (3)$$

where p_{sb} and ρ_{sb} are decision variables. p_{sb} is the transaction amount between seller s and buyer b and ρ_{sb} is the transaction price associated with p_{sb} . However, the price ρ_{sb} is out of control of seller s and buyer b but is decided by solving the market equilibrium problem. P_s is the excessive energy for sale of seller s , which comes from rooftop PV system, PV power station, wind turbine, or energy stored in batteries. λ^{sell} is FiT and λ^{cost} is the transaction cost, such as grid tariff for using the grid facilities. The objective function (Eq. 1) is seller's profit maximization problem. The first term represents the total revenue of trading with B energy buyers in the P2P market. The second term is the total revenue of selling energy to the main grid. Sellers can sell their energy to the main grid if they still have surplus energy after P2P market transaction. The third term is the transaction cost in the P2P market.

Constraint (Eq. 2) limits that the total P2P trading amounts should not be more than seller's initial surplus energy. Constraint (Eq. 3) imposes non-negativity condition on the P2P trading amount. v_s and ω_{sb} after the colon are dual variables of the constraints.

Buyer's Problem

A rational energy buyer b seeks contract amount p_{sb} with energy seller s to reach minimum energy cost. The optimal problem of buyer b is

$$\min : \sum_{s \in S} \rho_{sb} p_{sb} + \lambda_b^{\text{buy}} \left(D_b - \sum_{s \in S} p_{sb} \right) \quad (4)$$

$$\text{s.t.} : \left(D_b - \sum_{s \in S} p_{sb} \right) \geq 0 : \gamma_b \quad (5)$$

$$p_{sb} \geq 0 : \omega_{sb}, \forall s \in S \quad (6)$$

where p_{sb} and ρ_{sb} are also decision variables and have been defined in *Seller's Problem*. D_b is the total energy demand of energy buyer b . λ_b^{buy} is the price when the buyer purchases energy from the main grid. In this article, we assume the main grid charges energy buyers in a time-and-level-of-use (TLOU) structure, which will be presented in following content. The objective function (Eq. 4) is buyer's cost minimization problem. The first term denotes the total cost of trading with S energy sellers in the P2P market. The second term is the total cost of buying energy from the main grid. Buyers can buy energy from the main grid to satisfy their remaining demand after P2P trading.

Constraint (Eq. 5) shows that the total P2P trading amounts should not exceed buyer's demand. γ_b and ω_{sb} after the colon are dual variables of the constraints.

Time-And-Level-Of-Use Price

Energy buyers purchase energy from the main grid at the TLOU price, which consists of two dimensions: time of day and level of consumption (Gomez-Herrera and Anjos, 2019). The structure of TLOU is as follows:

$$\lambda_t^{\text{buy}} = \lambda_{0t}^{\text{buy}} + k_t D_t, \quad k_t \geq 0, D_t \geq 0 \quad (7)$$

where λ_t^{buy} is the TLOU price and $\lambda_{0t}^{\text{buy}}$ is the benchmark price in period t , respectively. $k_t D_t$ is a level-wise part in which D_t is the total energy demand satisfied by grid and k_t is a non-negative slope coefficient. Compared with time-of-use (TOU), such a price scheme can preclude rebound demand peaks when $\lambda_{0t}^{\text{buy}}$ changes because more consumption is accompanied by higher price. Besides, TLOU can also reduce demand fluctuation and benefit power system operation. In this article, the use of TLOU can also make sure the problem is convex.

Equilibrium Model

In summary, all the participants in the P2P market consider their own interest optimal problem at the same time. Sellers or buyers increase or lower the transaction price ρ_{sb} and they can reach mutually satisfactory price finally. In such a circumstance, the P2P market can be described as an equilibrium model:

$$\begin{cases} \text{seller's problem (1)}, s \in S \\ \text{buyer's problem (4)}, b \in B \end{cases} \quad (8)$$

where all participants' interests are taken into consideration and solved simultaneously.

Problem Reformulation

In equilibrium problem (Eq. 8), it is crucial that sellers and buyers have consistent decision variables p_{sb} and ρ_{sb} . However, the product term $\rho_{sb} p_{sb}$ makes problem (Eqs. 1, 4) nonconvex and intractable in the traditional fixed-point method. Reformulating the primal optimal problem to its KKT conditions is a probable way to solve the problem.

It is worth mentioning that the transaction price ρ_{sb} is beyond the control of both seller s and buyer b and will be endogenously determined at the market equilibrium point. We regard ρ_{sb} as a constant while acquiring KKT conditions of sellers and buyers.

The KKT condition of seller s is:

$$\begin{aligned} -\rho_{sb} + \lambda^{\text{sell}} + \lambda^{\text{cost}} + v_s - \omega_{sb} &= 0, \forall b \in B \\ 0 &\leq \left(P_s - \sum_{b \in B} p_{sb} \right) \perp v_s \geq 0 \\ 0 &\leq p_{sb} \perp \omega_{sb} \geq 0, \forall b \in B \end{aligned} \quad (9)$$

The expression $0 \leq a \perp b \geq 0$ means a and b are non-negative and at least one of them is 0. In vector notation, the $a \perp b$ means $a^T b = 0$.

The KKT condition of each buyer b at the TLOU price scheme is

$$\begin{aligned} \rho_{sb} - \left[2k_i \left(D_b - \sum_{s \in S} p_{sb} \right) + \lambda_0^{buy} \right] + \gamma_b - \bar{\omega}_{sb} &= 0, \forall s \in S \\ 0 &\leq \left(D_b - \sum_{s \in S} p_{sb} \right) \perp \gamma_b \geq 0 \\ 0 &\leq p_{sb} \perp \bar{\omega}_{sb} \geq 0, \forall s \in S \end{aligned} \quad (10)$$

Since the sellers and buyers have consistent values of ρ_{sb} and p_{sb} , the KKT condition (Eqs. 9, 10) can be put together, which forms a dual equilibrium problem (Eq. 11).

$$\begin{cases} \text{KKT condition (9), } s \in S \\ \text{KKT condition (10), } b \in B \end{cases} \quad (11)$$

Problem (Eq. 11) is composed of a set of linear and nonlinear constraints. The decision variable p_{sb} can be obtained by solving the equilibrium problem (Eq. 11) and the market clearing price ρ_{sb} is determined automatically in (Eq. 9) or (Eq. 10), where both the equations are same. In our model, ρ_{sb} is no less than the λ^{sell} plus λ^{cost} , otherwise sellers will quit the P2P market. The reason is that sellers can choose to trade with higher bidder.

However, the equilibrium problem (Eq. 11) is a nonlinear problem and intrinsically hard because of the existence of nonlinear complementary slackness constraints.

Big-M Method

To deal with the complementary slackness constraints in the equilibrium problem (Eq. 11), we introduce a big-M method proposed in Fortuny-Amat and Mccarl (1981). Take complementary slackness constraint in KKT conditions (Eq. 9) as an example:

$$0 \leq \left(P_s - \sum_{b \in B} p_{sb} \right) \perp v_s \geq 0 \quad (12)$$

If the primal constraint is not binding, its dual variable v_s is zero; similarly, if dual variable v_s is positive, the primal constraint is binding. To depict the character, we can introduce an auxiliary binary vector z and a constant parameter M and transform the nonlinear constraints into linear constraints. The dimension of z is compatible with S . The new constraints yield:

$$0 \leq \left(P_s - \sum_{b \in B} p_{sb} \right) \leq M(1 - z_s) \quad (13)$$

$$0 \leq v_s \leq Mz_s \quad (14)$$

where M is a manually selected parameter. The value of M deserves discussion. In one respect, it should be large enough to cover the maximum points of (Eqs. 13, 14); in other respect, a smaller value contributes to the convergence and saves computation time.

However, the above constraints lack an optimization problem. We create an MILP to implement constraints (Eqs. 13, 14):

$$\min : z_s \left(P_s - \sum_{b \in B} p_{sb} \right) + (1 - z_s)v_s \quad (15)$$

$$\text{s.t. (13), (14)} \quad (16)$$

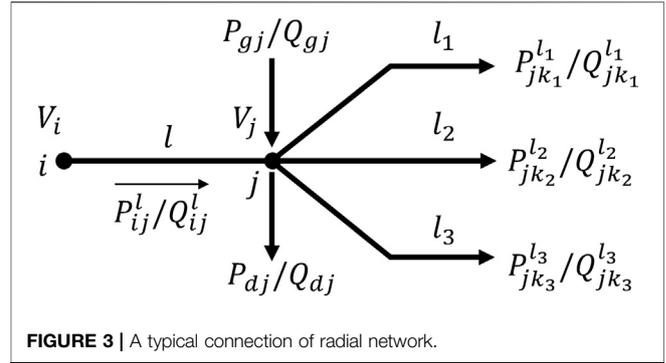

FIGURE 3 | A typical connection of radial network.

The objective function (Eq. 15) should be zero if the question is feasible. Otherwise, if the optimal value is positive, the complementary slackness constraint is violated. In the objective function, the product term $z_s v_s$ is composed of a binary variable and a dual variable. It can be linearized by an additional variable h_{s2} , subject to:

$$0 \leq h_{s2} \leq Mz_s; 0 \leq v_s - h_{s2} \leq M(1 - z_s) \quad (17)$$

Similarly, the reformulation can be applied to the first term $z_s \left(P_s - \sum_{b \in B} p_{sb} \right)$.

$$\begin{aligned} 0 &\leq h_{s1} \leq M(1 - z_s) \\ 0 &\leq \left(P_s - \sum_{b \in B} p_{sb} \right) - h_{s1} \leq Mz_s \end{aligned} \quad (18)$$

Finally, the objective function (Eq. 15) can be written as an MILP:

$$\begin{aligned} \min : & h_{s1} + v_s - h_{s2} \\ \text{s.t.} & (16), (17), (18) \end{aligned} \quad (19)$$

Feasible solution can be obtained by solving above MILP through the commercial optimization problem solver, such as MOSEK.

OPTIMAL POWER FLOW WITH TRANSACTIVE ENERGY

In this section, we implement P2P energy sharing in the optimal power flow problem of a microgrid-based distribution network. A distribution system operator (DSO) controls the distribution network with an operation goal to minimize the total energy cost. Many distribution networks are radial network with tree topology. The typical connection of a radial network is shown in Figure 3. Without loss of generality, a peer in the P2P market is a bus in distribution network, whose role is, e.g., a traditional energy consumer, a prosumers with DERs, or a local solar power station, etc. Branch flow model (BFM) is used in radial distribution power grid (Baran and Wu, 1989b) (Baran and Wu, 1989a). The radial network can be described by a graph $G = [N, L]$, where N and L are the bus set and distribution line set, respectively.

Branch Flow Model

The mathematical formulation of BFM is described as follows, with an objective function to minimize total energy generation cost. x is the feasible set of BFM solutions.

$$\min : F(x) = \sum_{i \in N} a_i P_{gi}^2 + b_i P_{gi} + c_i \tag{20}$$

$$s.t. : P_{ij}^l - r_{ij}^l I_{ij}^l + P_{gi} - P_{dj} = \sum_{k \in c(j)} P_{jk}^l, \forall j \in N, l \in L \tag{21}$$

$$Q_{ij}^l - x_{ij}^l I_{ij}^l + Q_{gj} - Q_{dj} = \sum_{k \in c(j)} Q_{jk}^l, \forall j \in N, l \in L \tag{22}$$

$$V_j = V_i - 2(P_{ij}^l r_{ij}^l + Q_{ij}^l x_{ij}^l) + (z_{ij}^l)^2 I_{ij}^l, \forall l \in L \tag{23}$$

$$V_i I_{ij}^l = (P_{ij}^l)^2 + (Q_{ij}^l)^2, \forall l \in L \tag{24}$$

$$P_{gi}^n \leq P_{gi} \leq P_{gi}^m, \forall i \in N \tag{25}$$

$$Q_{gi}^n \leq Q_{gi} \leq Q_{gi}^m, \forall i \in N \tag{26}$$

$$V_i^n \leq V_i \leq V_i^m, \forall i \in N \tag{27}$$

$$\sqrt{(P_{ij}^l)^2 + (Q_{ij}^l)^2} \leq S_l, \forall l \in L \tag{28}$$

where constraints (Eqs. 21, 22) are bus active/reactive power balance condition. Constraint (Eq. 23) is the forward voltage drop in branch l . The apparent power injection at the head bus of branch l is described in (Eq. 24). In proposed BFM, the initial bus is i and branch l is defined as the line between bus i and j . For constant parameters, r_{ij}^l/x_{ij}^l is the resistance/reactance of branch l . $z_{ij}^l = \sqrt{(r_{ij}^l)^2 + (x_{ij}^l)^2}$ is the impedance value. P_{dj}/Q_{dj} are fixed active/reactive power demand at bus j . For variables, V_i/V_j and I_{ij}^l are square voltage and current magnitude. P_{ij}^l/Q_{ij}^l presents the active/reactive power flow in branch l . P_{gi}/Q_{gi} denotes active/reactive power generation at bus j . The right-hand part of (Eq. 21) and (Eq. 22) are power flow started with bus j .

Constraints (Eqs. 25–28) are the physical network operating constraints, which represent the active and reactive generation capacities, nodal voltage constraint, and power flow limits in each line.

In the above constraints (Eq. 24) is a quadratic equation, which makes the BFM nonlinear and nonconvex. To solve the nonconvex problem Farivar and Low (2013) proposed a second-order cone program (SOCP) method to make convex relaxation, which replaces the equality constraint (Eq. 24) with the following inequality constraint in a canonical form:

$$\left\| \begin{matrix} 2P_{ij}^l \\ 2Q_{ij}^l \\ I_{ij}^l - V_i \end{matrix} \right\| \leq I_{ij}^l + V_i \tag{29}$$

Such a SOCP convex relaxation is exact for BFM under some mild conditions, such as the objective function is convex and cost is strictly increasing in line losses. However, the relaxation may be inexact if the objective function violates the above mild conditions, thus resulting in infeasible solution.

Denote the BFM constraints with SOCP concisely as Cons-BFM.

Feasibility Recovery

To make sure the convex relaxation is exact Wei et al. (2017) proposed a method based on the convex-concave program to evaluate the initial SOCP result and run the feasibility recovery procedure if SOCP is inexact. Guo et al. (2020) made some improvement based on the method, gaining better convergence performance. Detailed method introduction is as follows:

Denote Following Convex Quadratic Functions

$$\begin{aligned} f_l(x) &= V_i I_{ij}^l, \forall l \in L \\ g_l(x) &= (P_{ij}^l)^2 + (Q_{ij}^l)^2, \forall l \in L \end{aligned} \tag{30}$$

Define a gap function to show the gap in (Eq. 24) caused by the SOCP relaxation at x^* :

$$Gap(x^*) = \sum_l [f_l(x^*) - g_l(x^*)] \tag{31}$$

where x^* is the solution from BFM with SOCP convex relaxation. If the gap does not exceed predetermined tolerance value ϵ , the relaxation is exact. Otherwise, operate the following feasibility recovery procedure to obtain exact optimal solution:

Algorithm 1: Feasibility Recovery Procedure

1. Set an initial penalty coefficient $\rho^1 > 0$, a penalty growth rate $\tau > 1$, and a penalty upper bound ρ^M . Let the initial iteration index $k = 1$, and the initial point $x^1 = x^*$.
 2. Form linear approximation of $g_l(x)$ at x^k : $\bar{g}_l(x, x^k) = g_l(x^k) + \nabla g_l(x^k)^T (x - x^k)$
And solve the following approximation of $g_l(x)$ at x^k
 $\min F(x) + \rho^k \sum_l s_l$
s.t. Cons - BFM; $s_l \geq 0, \forall l \in L$;
 $f_l(V_i^k, I_{ij}^l) - \bar{g}_l(x, x^k) \leq s_l, \forall l \in L$
- where s_l is an auxiliary variable and the optimal solution is (x^{k+1}, s^{k+1})
3. If the relaxation gap $Gap(x^{k+1}) \leq \epsilon$, terminate and report the optimal solution; otherwise, update $\rho^{k+1} = \min(\tau \rho^k, \rho^M), k \leftarrow k + 1$, and go to step 2

A Two-Stage Method

P2P market transactions should be implemented in physical power system network. First, the aggregator in the P2P market collects the transaction information and solves the P2P equilibrium problem. Second, the aggregator submits P2P transaction results to DSO. The DSO solves an optimal power flow problem in BFM to minimize total energy cost under network operating constraints.

Figure 4 shows how P2P transaction is embedded in the physical distribution network. After reaching an agreement in the P2P financial network, the supply buses inject energy into physical network and receive cash payment while the demand buses absorb energy from the physical network and pay for this transactive energy.

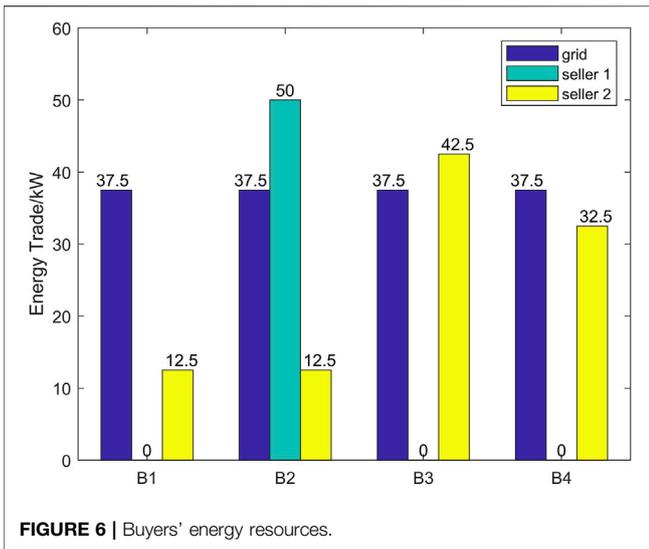

FIGURE 6 | Buyers' energy resources.

There are three generators located in buses 2, 3, and 4 respectively. The detailed line data and generator parameters are listed in Tables 2, 3. The reference value is 1 MVA and all the parameters and results are given in p.u. The voltage magnitude limits are $V_i^n = 0.9$, $V_i^m = 1.05$. The initial power demands at buses are $p_i^d = 0.5$, $q_i^d = 0.1$.

Numerical Result

In the first stage, after solving the equilibrium problem, we can obtain the following P2P market model solution.

TABLE 4 | Comparison of total cost and Revenue/\$.

Without P2P		With P2P		Market benefit
Cost	Revenue	Cost	Revenue	
173.8	60	166.875	84.75	31.675

Figure 6 depicts where buyers purchase their energy. Without P2P transaction, they can only satisfy their demands through the main grid. With the P2P market, consumers can allocate their demand between main grid and P2P market to reduce their costs. In our test case, all buyers purchase same quantity from grid and all P2P transaction prices are 0.575\$/kWh, which is also the main grid marginal price. As a result, it is no difference for the buyer to choose whom to trade in the P2P market. The result is reasonable because if a buyer offers a higher price, all sellers will trade with him and other buyers will also improve their prices successively; if a buyer offers a lower price, he will loss all sellers and a rational participant will avoid the option. In this condition, the equilibrium price gradually converges to the highest main grid marginal price.

Figure 7 shows the buyers' costs and sellers' revenues comparison between the two scenarios, without and with the P2P market. The left one shows that all buyers benefit from the P2P market and have less cost, in which B2 has the most significant reduction in total energy cost because he has the largest amount consumption in the P2P market. Sellers also earn more profit through P2P sharing.

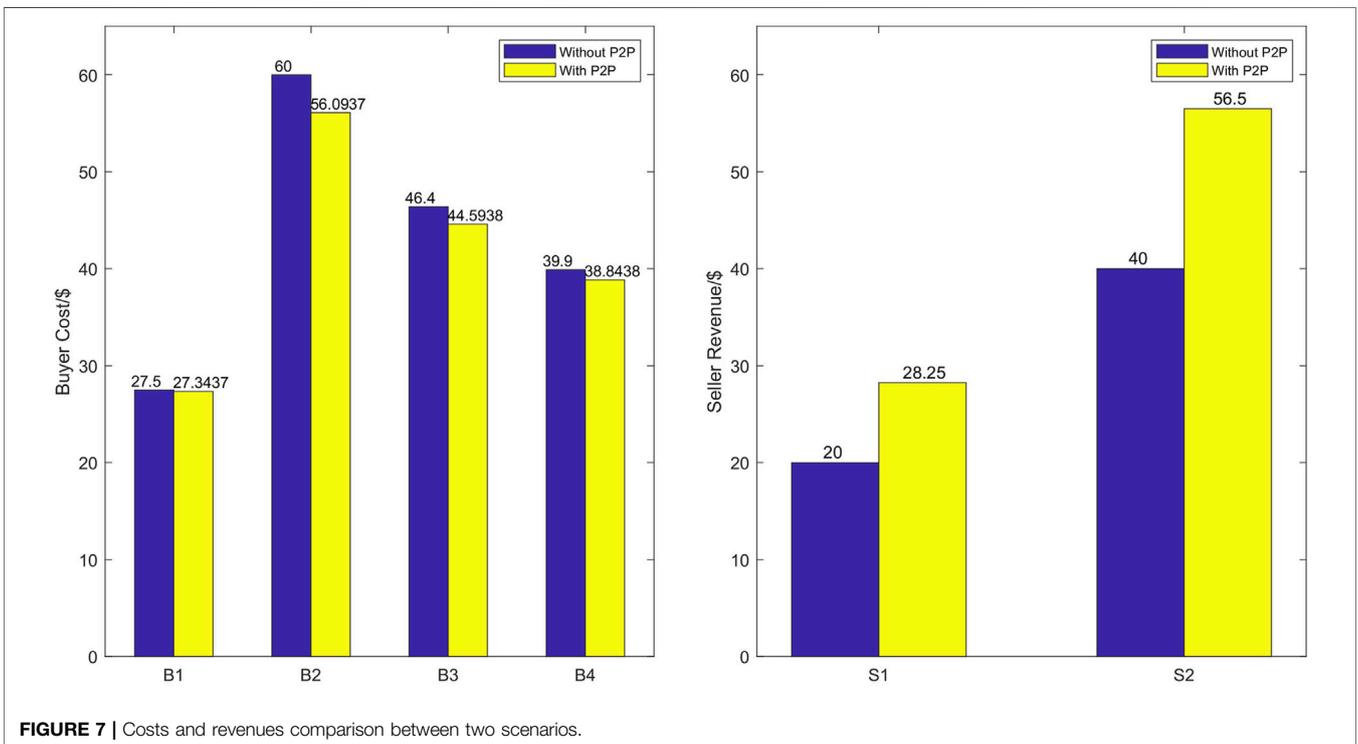

FIGURE 7 | Costs and revenues comparison between two scenarios.

TABLE 5 | Comparison of different value of M.

Value of M	10	50	90	100	150	200	500	1,000
Time/s	Fail	Fail	Fail	0.35	0.37	0.37	0.39	0.42
Market Benefit/\$	Fail	Fail	Fail	31.675	31.675	31.675	31.675	31.675

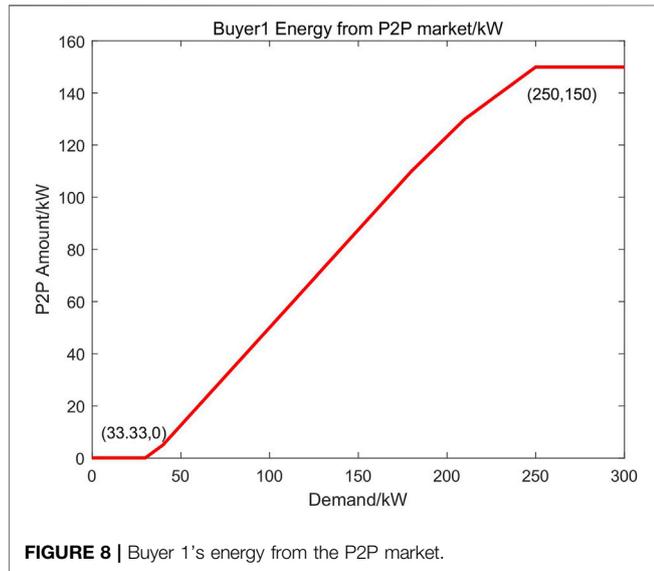

FIGURE 8 | Buyer 1's energy from the P2P market.

Finally, **Table 4** summarizes the total cost and revenue of P2P market participants during the trading period. Owing to the introduction of P2P market, the sellers and buyers can discover transaction price in P2P trading. The price is not less than the FiT value and not more than TLOU. Therefore, buyers' cost decreases and sellers' revenue increases, with an improvement of \$ 31.675 in market benefit. The local welfare gets improvement compared with market without the P2P market.

Discussion of Parameter M

In *Big-M Method*, we claim the value of parameter M is manually specified. It should be neither too big nor too small. In a benchmark case study, the numerical value of M is 150. To find out the performance of the optimization impacted by the value of M, we change the numerical value of M from 10 to 1,000 and record their feasibility and calculation time of equilibrium problem. The results are provided in **Table 5**.

In **Table 5**, fail means the equilibrium problem is infeasible in solver MOSEK. In our benchmark test, the value of M should not be less than 100, which is also the maximum value of seller's supply and buyer's demand. When M is equal to or larger than maximum supply or demand value, the results of market benefit are identical. In terms of calculation time, we can find time increases with M's value improvement. In view of the above finding, we can obtain some instructions about the selection of M. On one hand, it should not be less than the maximum value of

TABLE 6 | Comparison of FRP and KNITRO.

Tolerance value ϵ	FRP			KNITRO	
	F(x)	Time/s	Iteration	F(x)	Time/s
10^{-10}	12.74	5.69	11	12.65	0.85
10^{-9}	12.65	0.71	0		
10^{-8}	12.65	0.61	0		
10^{-6}	12.65	0.52	0		
10^{-4}	12.65	0.55	0		

seller's supply and buyer's demand. On the other hand, it should not be too large to save calculation time.

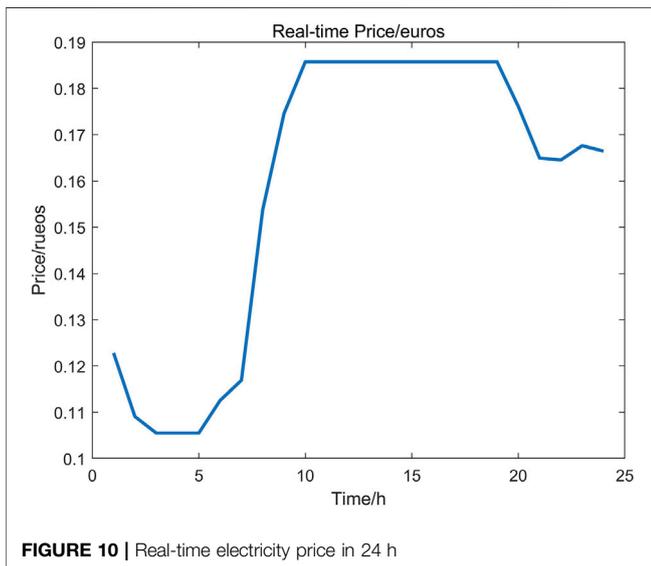

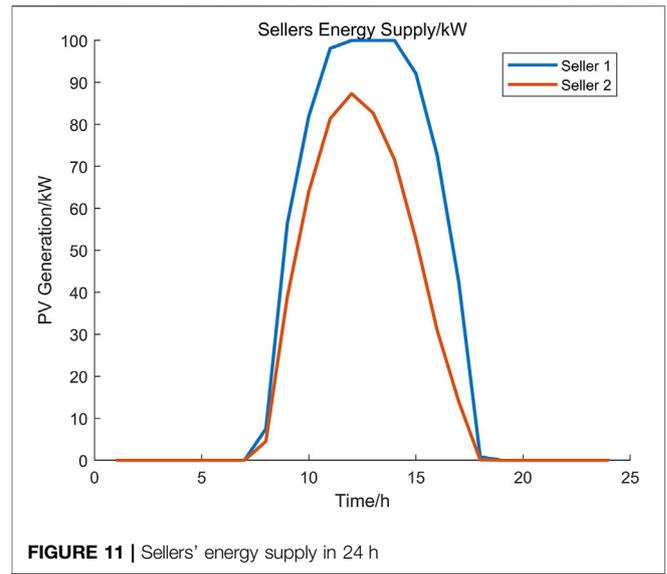

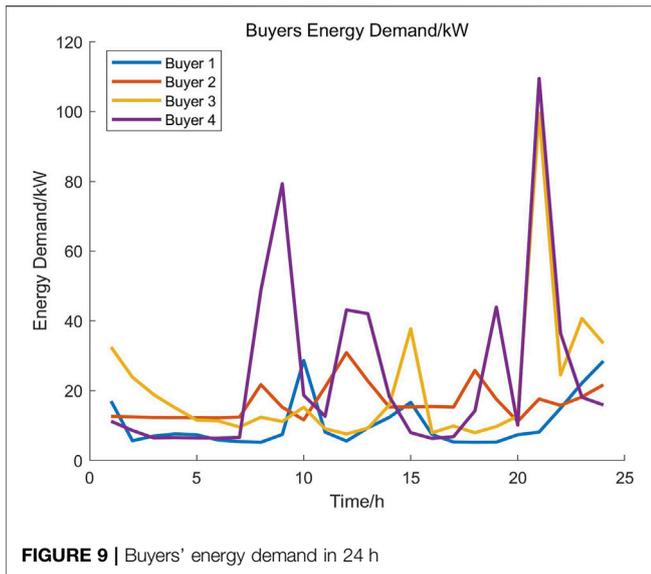

Sensitivity Analysis

We keep other participants' supply and demand and change buyer 1's demand. The buyer 1' energy bought from P2P market also changes accompanied with demand increase, as shown in **Figure 8**. And the important turning points (33.33, 0), (250, 150) are declared in **Figure 8**. If the demand is less than 33.33kW, compared with other energy buyers, buyer 1 faces relatively lower TLOU price in the grid market and he has no incentive to offer a much higher price in the P2P market, so he will not buy any energy from the P2P market. If the demand is higher than 33.33kW and less than 250kW, buyer 1 will be charged at a higher TLOU price by grid, so he will buy energy from the P2P market and compete with participants, thus leading to an equilibrium problem. If the demand is higher than 250kW, buyer 1 faces a much higher TLOU price, so he will buy as much energy in the P2P market as possible. In such a scenario, buyer 1 has market power and consumes all P2P energy.

Performance of Feasibility Recovery Procedure

In this subsection, we evaluate the performance of FRP. In the first stage, the aggregator solves the equilibrium problem in the P2P market and submits P2P transaction information to DSO. In the second stage, the DSO solves BFM with SOCP relaxation. When the initial SOCP relaxation is inexact and the relaxation gap exceeds predetermined tolerance value $\epsilon = 10^{-6}$, the initial solution is infeasible and will be passed to FRP. In FRP, we set $\rho^1 = 10^{-4}$, $\tau = 2$, $\epsilon = 10^{-6}$, and $\rho^M = 10$. The initial point is the infeasible solution from BFM with SOCP relaxation.

To evaluate the performance of the solution from FRP, we compare it with a solution from NLP solver KNITRO, which can handle the nonconvex optimization problem. The results are

shown in **Table 6**. $F(x)$ is the total electricity generation costs in BFM.

In FRP, we change the value of ϵ and investigate the algorithm performance. When $\epsilon = 10^{-10}$, the SOCP is

inexact and the initial result is passed to FRP, which needs 11 iterations to converge. The average time is 0.5–0.6 s per iteration in FRP. However, $\epsilon = 10^{-10}$ is a fairly strict criterion on SOCP relaxation. If we increase the value of ϵ , the SOCP relaxation is exact and will not use FRP. The final result is 12.65. In KNITRO, the average processing time is 0.85 s and the result is 12.65.

In conclusion, we can observe that in a 6-bus distribution network, SOCP relaxation is exact when the tolerance value ϵ is not extremely strict, and the solutions of FRP and KNITRO are the same. When we further reduce tolerance value, the SOCP relaxation is inexact and the FRP needs 11 iterations to converge. The result is slightly different from 12.65 because such strict tolerance is not applicable in real world and may affect the final solution. In general, the value range of ϵ is $10^{-6} \sim 10^{-4}$. We provided more detailed discussions about FRP in our previous work (Wei et al., 2017).

Additional Case Study

To further validate our proposed P2P model, we provide a realistic case study simulated over one day with 1 h time-step. We collect four realistic energy buyers' demand and real-time electricity price from 200 Irish residents over the year of 2009, as shown in **Figures 9, 10**. Energy sellers' renewable energy

TABLE 7 | Comparison of participant's cost and revenue/euros.

Participants		Without P2P	With P2P	Benefit	Benefit/Without P2P (%)
Seller's revenue/euros	1	97.13	101.25	4.12	4.24
	2	68.234	70.96	2.72	3.99
Buyer's cost/euros	1	45.23	38.95	6.28	13.88
	2	72.62	62.00	10.62	14.62
	3	95.83	87.76	8.07	8.42
	4	128.53	110.21	18.32	14.25

generation curve is shown in **Figure 11**, which comes from the solar PV simulation data in Ireland. All data set has been processed and scaled to benchmark parameter setting, which can be found in our **Supplementary Material**. The constant coefficient $k_t = 0.001$ in time-and-level of use price. And the FiT is proportionate to real-time price, such as 0.7. Transaction cost $\lambda^{cost} = 0.005$.

Table 7 summarizes every P2P market participant's cost and revenue comparison during one day. Both energy sellers and buyers can benefit from the introduction of the P2P market. The additional case study using realistic data further validates our proposed P2P model, which can benefit all participants.

CONCLUSION

In this article, we have proposed a novel P2P market framework to model the equilibrium of P2P transactive energy. The transaction price is determined endogenously by solving the KKT conditions of all peers' optimization problem. The equilibrium condition can be transformed to an MILP which can be processed by commercial solvers. The transaction energy flow information is further submitted to the distribution system operator and used to solve optimal power flow, so that network operation constraints can be guaranteed. The case study demonstrates that our proposed P2P market benefits all participants. The society also benefits from the P2P market.
