$\gamma\delta$ T cells are a minor population (~5%) of CD3 T cells in the peripheral blood, but abundant in other anatomic sites such as the intestine or the skin. There are two major subsets of $\gamma\delta$ T cells: those that express V δ 1 gene, paired with different V γ elements, abundant in the intestine and the skin, and recognize the major histocompatibility complex (MHC) class I-related molecules such as MHC class I-related molecule A, MHC class I-related molecule B, and UL16-binding protein expressed on many stressed and tumor cells. Conversely, $\gamma\delta$ T cells expressing the V δ 2 gene paired with the V γ 9 chain are the predominant (50–90%) $\gamma\delta$ T cell population in the peripheral blood and recognize phosphoantigens (PAGs) derived from the mevalonate pathway of mammalian cells, which is highly active upon infection or tumor transformation. Aminobisphosphonates (n-BPs), which inhibit farnesyl pyrophosphate synthase, a downstream enzyme of the mevalonate pathway, cause accumulation of upstream PAGs and therefore promote $\gamma\delta$ T cell activation. $\gamma\delta$ T cells have distinctive features that justify their utilization in antitumor immunotherapy: they do not require MHC restriction and are less dependent than $\alpha\beta$ T cells on co-stimulatory signals, produce cytokines with known antitumor effects as interferon- γ and tumor necrosis factor- α and display cytotoxic and antitumor activities *in vitro* and in mouse models *in vivo*. Thus, there is interest in the potential application of $\gamma\delta$ T cells in tumor immunotherapy, and several small-sized clinical trials have been conducted of $\gamma\delta$ T cell-based immunotherapy in different types of cancer after the application of PAGs or n-BPs plus interleukin-2 *in vivo* or after adoptive transfer of *ex vivo*-expanded $\gamma\delta$ T cells, particularly the V γ 9V δ 2 subset. Results from clinical trials testing the efficacy of any of these two strategies have shown that $\gamma\delta$ T cell-based therapy is safe, but long-term clinical results to date are inconsistent. In this review, we will discuss the major achievements and pitfalls of the $\gamma\delta$ T cell-based immunotherapy of cancer.

Keywords: $\gamma\delta$ T cells, immunotherapy, adoptive transfer, Zoledronate, immunoevasion

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; BTN, butyrophilin; BrHPP, bromohydrin pyrophosphate; CAR, chimeric antigen receptor; CSC, cancer stem cell; DR5, death receptor 5; Fc, fragment crystallizable; FcR, fragment crystallizable receptor; Fv, variable fragment; GMP, good manufacturing practice; HMGCR, 3-hydroxy-3-methylglutaryl-CoA reductase; IFN, interferon; IL, interleukin-; iPSC, inducible pluripotent stem cells; mAbs, monoclonal antibodies; MHC, major histocompatibility complex; MICA, MHC class I-related molecule A; MICB, MHC class I-related molecule B; MM, multiple myeloma; n-BP, aminobisphosphonate; NCR, natural cytotoxicity receptors; NHL, non-Hodgkin lymphoma; NKG2D, natural-killer group 2, member D; NSCLC, non-small cell lung cancer; PAG, phosphoantigen; PD-1, programmed death-1; PD-L1, programmed death-ligand 1; TCR, T cell receptor; TFH, follicular T helper; TGF, transforming growth factor; Th, T helper; TIGIT, T-cell immunoreceptor with Ig and ITIM domains; TNF, tumor necrosis factor; TRAIL, TNF-related apoptosis-inducing ligand; Treg, T regulatory; ULBP, UL16-binding protein; VEGF, vascular endothelial growth factor.

INTRODUCTION

T cells carrying the $\gamma\delta$ T cell receptor (TCR) are a minor lymphocyte population that accounts for 2–5% of CD3 T cells in the peripheral blood, but predominate in several anatomic sites such as the intestine and the skin. There are two major $\gamma\delta$ T cell subsets in humans which are distinguished based on the δ chain they use to make their TCR: T cells expressing the V δ 2 gene paired with the V γ chain (V γ 9) are the great majority of the $\gamma\delta$ T cell population in the peripheral blood and secondary lymphoid organs of healthy individuals. In contrast, $\gamma\delta$ T cells expressing the V δ 1 gene, paired off with different V γ elements, are the predominant $\gamma\delta$ T cell subset in epithelia (skin and mucosa). Finally, a third subset of $\gamma\delta$ T cells expressing the V δ 3 chain abound in the liver (1).

V δ 1 T cells have a largely private TCR repertoire with different clonotypes present in each individual, while the V γ 9V δ 2 repertoire has limited complexity with invariant V γ 9-JP sequences common to multiple individuals, and many CDR3 δ 2 sequences although are relatively private compared with TCR γ 9 lengths, are shared between individuals (2, 3). Therefore, the V γ 9V δ 2 T cell population expresses a TCR with very limited variability, suggesting recognition of a limited set of antigens.

Antigen recognition by $\gamma\delta$ T cells is a field of intense research. V γ 9V δ 2 T cells recognize non-peptidic phosphorylated intermediates of the non mevalonate pathway of isoprenoid biosynthesis called phosphoantigens (PAGs), in the absence of processing, presentation, and major histocompatibility complex (MHC) restriction (4). PAGs are synthesized in mammalian cells through the mevalonate pathway (5), but PAG concentrations required for V γ 9V δ 2 T cell activation are not achieved in physiological conditions, but only after infections or tumor transformation (6). Therefore, from this point of view, the V γ 9V δ 2 TCR works in a similar way to a pattern-recognition receptor, which senses metabolic changes found in transformed or infected cells.

Intracellular PAG levels can be modulated by drugs. Thus, aminobisphosphonates (n-BPs) such as Zoledronate, widely used in the clinic for the treatment of osteoporosis and bone metastasis, inhibit farnesyl pyrophosphate synthase (FPPS), a downstream enzyme of the mevalonate pathway, thereby causing accumulation of upstream PAGs and thus favoring V γ 9V δ 2 T cell activation (7, 8). Conversely, statins inhibit hydroxy-methylglutaryl-CoA reductase (HMGCR), the upstream enzyme of the mevalonate pathway, and significantly reduce PAGs production and V γ 9V δ 2 T cell activation (9).

V δ 1 T cells recognize MHC class I-related molecule A (MICA), MHC class I-related molecule B (MICB), and UL16-binding proteins (ULBPs) molecules, a group of proteins expressed on stressed and tumor cells (10, 11), and the MHC-related class Ib molecules CD1c and CD1d, which are typically involved in glycolipid presentation (12, 13). However, as V δ 1 T cells constitutively express natural-killer group 2, member D (NKG2D), the “true” receptor of MICA and MICB, it is still to be determined if V δ 1 T cell recognition of MICA and MICB is mediated by the TCR or by NKG2D. Moreover, V δ 1 T cells can also be activated by engagement of natural cytotoxicity receptors (NCRs, such as NKp30 and NKp44) by yet unidentified ligands (14). Similar to

V δ 1 T cells, V δ 3 T cell ligands are poorly known and there is only one study showing that these cells are activated by CD1d possibly bound to a yet unidentified glycolipid (15).

Phosphoantigens recognition by V γ 9V δ 2 T cells requires butyrophilin (BTN) 3A1 (also called CD277) (16), but how PAGs interact with BTN3A1 and how the PAG/BTN3A1 complex in turn interacts with the V γ 9V δ 2 TCR is a matter of debate. Initial studies by Vavassori et al. (17) found a PAG-binding site located in the extracellular domain of BTN3A1, but a subsequent study by Adams and coworkers (18) found that PAGs bind to the intracellular domain of BTN3A1, leading to the possibility that intracellular PAGs provoke a conformational change of BTN3A1, which allows its extracellular domains to interact with the reactive V γ 9V δ 2 TCR.

V γ 9V δ 2 T cells express several cell surface molecules correlated with distinct functional differentiation phenotypes. The combined use of CD27 and CD45RA permits identification of “naive” and “central memory” subsets of V γ 9V δ 2 T cells (T_{Naive} , CD45RA⁺CD27⁺; T_{CM} , CD45RA⁻CD27⁺) that circulate between the blood and secondary lymphoid organs, but are excluded from peripheral tissues and lack effector function; and “effector memory” (T_{EM} , CD45RA⁻CD27⁻) and “terminally differentiated” (T_{EMRA} , CD45RA⁺CD27⁻) subsets that circulate between the blood and peripheral tissues, are recruited to sites of inflammation and immediately perform effector function (19).

While T_{Naive} and T_{CM} cells readily respond to PAG stimulation, T_{EM} and T_{EMRA} respond to homeostatic cytokines as interleukin (IL)-15 (20) and may acquire highly diverse effector functions in the presence of polarizing cytokines (21). In general, circulating V γ 9V δ 2 T cells have a Th1 pattern of cytokine production (21), but under certain conditions they polarize to Th2 (22, 23), Th17 (24–26), follicular T helper (27, 28), Th9 (29), and T regulatory (Treg) cells (30). Such a flexibility emphasizes the capacity of V γ 9V δ 2 T cells to efficiently participate to immune responses to different antigen challenges.

RATIONALE FOR HARNESSING $\gamma\delta$ T CELLS IN CANCER IMMUNOTHERAPY

In the following section, we will briefly summarize the rationale for harnessing $\gamma\delta$ T cells in cancer immunotherapies.

- (1) The major objective of immunotherapy is the generation of a long-lasting efficient antitumor response, particularly mediated CD8 cytotoxic T cells, but also by CD4 T cells (31, 32). Nonetheless, despite efforts, durable responses are only rarely achieved and moreover tumors often develop strategies to escape immune responses (33). In contrast to CD4 or CD8 T cells, $\gamma\delta$ T cells have unique features which make them good candidates for effective tumor immunotherapy: they do not require MHC restriction and co-stimulation and they recognize antigens shared by a variety of stressed and tumor cells, making it possible for a single $\gamma\delta$ T cell to target a vast array of tumor cells. Hence, recognition of commonly shared tumor antigens in the absence of MHC restriction provides the rationale for application of $\gamma\delta$ T cell-based

- therapy to a wide range of tumors and in patients with different MHC molecules (34).
- (2) A distinctive feature of T lymphocytes equipped with anti-tumor potential is their ability to secrete appropriate cytokines. Typically, activated $\gamma\delta$ T cells secrete interferon (IFN)- γ and tumor necrosis factor (TNF)- α , two cytokines with cytotoxic and antitumor activities (35–37).
 - (3) A large body of studies have demonstrated that $\gamma\delta$ T cells kill *in vitro* a broad array of tumor cells, while sparing normal cells (34), and display antitumor activity in mouse models *in vivo* (34). The cytotoxic activity of $\gamma\delta$ T cells against tumor cells is strictly dependent on augmented production of PAg (38), which partly relies on increased expression of HMGCR (38). Moreover, intracellular PAg levels can be substantially increased by n-BPs (13–15, 38), thereby

promoting activation of V γ 9V δ 2 T cells (38). Killing may also be reinforced by the tumor cell expression of NCRs (39) and/or NKG2D ligands (such as MICA, MICB, and ULBPs) (40–42) or by antibody-dependent cell-mediated cytotoxicity (ADCC) mediated by CD16 interacting with antibody-coated tumor cells (43) (**Figure 1**).

Whatever the mechanism of $\gamma\delta$ T cell recognition of tumor target cells, killing involves the perforin/granzyme (44) and TNF-related apoptosis-inducing ligand (TRAIL) (45) pathways, and Fas/FasL interaction (46). The choice of the mechanism is mostly dictated by the nature of the target cell itself (47). For instance, we previously found that colon cancer stem cells (CSCs), which are typically resistant to $\gamma\delta$ T cell-mediated cytotoxicity, are efficiently killed upon sensitization with Zoledronate (48). Killing of

FIGURE 1 | Tumor cell ligands recognized by human $\gamma\delta$ T cells. The upper and lower panels show stimulatory and inhibitor signals delivered by tumor cells to V δ 1 (left) and V δ 2 (right) $\gamma\delta$ T cell subsets. V γ 9V δ 2 T cells recognize *via* their TCR non-peptidic phosphoantigens (PAgs) and BTN3A1, while V δ 1 T cell receptor (TCR) ligands are not defined yet. Both $\gamma\delta$ T cell subsets constitutively express surface natural cytotoxicity cell receptors (NCRs) that bind MICA/MICB and ULBPs, frequently expressed on tumor cells. Upon activation, V γ 9V δ 2 T cells express fragment crystallizable receptor for IgG (Fc γ RIII; also known as CD16) that can bind therapeutic antibodies and mediate antibody-dependent cell-mediated cytotoxicity phenomena. Inhibitor signals delivered by tumor cells have not been well characterized. MICA/B, MHC class I-related chain A/B; ULBP, UL16-binding protein; BTN3A1, butyrophilin 3A1.

Zoledronate-treated colon CSCs was abrogated by anti-CD3 or anti- $\gamma\delta$ TCR monoclonal antibodies (mAbs), or mevas-tatin, which inhibits HMGR and prevents PAg accumulation, and by Concanamycin A that blocks degranulation, indicating that V γ 9V δ 2 T cells recognize Zoledronate-treated colon CSCs by the TCR interacting with PAg and utilize the perforin pathway to kill them (48). The colon CSCs are usually resistant also to chemotherapy, but we unexpectedly found that pretreatment with 5-Fluorouracil and Doxorubicin sensitizes colon CSCs to killing by V γ 9V δ 2 T cells. However, killing of chemotherapy-sensitized colon CSCs by V γ 9V δ 2 T cells was inhibited by anti-NKG2D mAb and by blocking TRAIL interaction with its death receptor 5 (DR5), indicating that V γ 9V δ 2 T cells recognize chemotherapy-treated colon CSCs by NKG2D interaction with MICA/B or ULBPs and kill them through mechanisms involving TRAIL interaction with DR5 (49).

- (4) In order for T lymphocytes to interact with tumor cells they should be capable to infiltrate tumors. Tumor-infiltrating leukocytes are found in a several different solid tumors (50) and include both myeloid (granulocytes, macrophages, and myeloid-derived suppressor cells) and lymphoid (T, B, and NK) cells, each of which impacts differently on tumor prognosis (51). Tumor-infiltrating V γ 9V δ 2 T lymphocytes have been detected in several types of cancer (52), but their clinical relevance has remained long obscure because of inconsistent results. However, analysis of expression signatures from ~18,000 human tumors with overall survival outcomes across 39 malignancies identified tumor-infiltrating $\gamma\delta$ T cells as the most significant favorable cancer-wide prognostic signature (53). Similarly, our own results of data mining transcriptomes and clinical files from a large cohort of colorectal cancer samples ($n = 585$), revealed that the 5-year disease-free survival probability was significantly higher in patients with high number of tumor-infiltrating $\gamma\delta$ T cells (54).
- (5) Two synthetic drugs, the PAg bromohydrin pyrophosphate (BrHPP) and the n-BP Zoledronate, activate human V γ 9V δ 2 T lymphocytes *in vitro* and in clinical trials *in vivo*. BrHPP is produced as good manufacturing practice grade for use in humans under the name Phosphostim (55). Zoledronate, a third generation n-BP used to treat osteoporosis and bone metastasis, inhibits FPPS and causes accumulation of endogenous PAg which thus reach the threshold required for V γ 9V δ 2 T cell activation (56). Second generation n-BPs, such as Pamidronate, Alendronate, and Risedronate, have similar activities of Zoledronate but at higher concentrations (55). Of note, *in vitro* and *in vivo* expansion of V γ 9V δ 2 T cells by either PAg or n-BPs requires exogenous IL-2.

Overall, the above functional aspects of $\gamma\delta$ T cell biology, have led to their utilization in cancer immunotherapy, and two strategies have been developed: (1) *in vivo* administration of PAg or n-BPs that activate V γ 9V δ 2 T cells and (2) adoptive transfer of *ex vivo*-expanded V γ 9V δ 2 T cells. Several small-sized phase I clinical trials have assessed the safety and efficacy of these two strategies in patients with various tumor types, and available data suggest that V γ 9V δ 2 T cell-based immunotherapy is well

tolerated and may give some clinical benefit to patients, thus providing a proof of principle for its utilization in addition to conventional therapies (57).

In the following sections, we will review the major achievements and pitfalls of the V γ 9V δ 2 T cell-based immunotherapy.

RESULTS FROM CLINICAL TRIALS BASED ON *IN VIVO* ACTIVATION OF $\gamma\delta$ T CELLS

A survey of clinical trials based on *in vivo* activation of $\gamma\delta$ T cells in different types of cancer is shown in **Table 1**.

Since B-cell type non-Hodgkin lymphoma (NHL) and multiple myeloma (MM) are highly sensitive to lysis by V γ 9V δ 2 T cells *in vitro*, a pioneering study by Wilhelm and colleagues (58) analyzed *in vivo* the toxicity, V γ 9V δ 2 T cell activation and anti-lymphoma activity of Pamidronate and IL-2 in 19 patients with NHL or MM. Ten patients received Pamidronate followed by IL-2, but neither V γ 9V δ 2 T cell activation nor response to treatment were observed. Therefore, a second group of nine patients was selected for *in vitro* V γ 9V δ 2 T cell response to Pamidronate and IL-2 and was treated with Pamidronate followed by increasing doses of IL-2. Significant *in vivo* expansion of V γ 9V δ 2 T cells was detected in this group, and three patients achieved objective responses. This was the first study demonstrating activation of V γ 9V δ 2 T cells in patients with B-cell lymphomas by Pamidronate and low-dose IL-2 was well tolerated and induced a clinical response; moreover, the immunologic and clinical outcome could be nicely predicted by V γ 9V δ 2 T cell proliferation *in vitro*.

At the same time as the aforementioned study, we performed an observational study in nine cancer patients with bone metastases to determine if Zoledronate affected activation and maturation of circulating V γ 9V δ 2 T cells *in vivo* (8). The results of that study showed that Zoledronate-induced the *in vivo* differentiation of V γ 9V δ 2 T cells to the T_{EM} subset producing IFN- γ . Therefore, and based on this, we then conducted a phase I clinical trial in 18 patients with metastatic hormone-refractory prostate cancer (59). Patients were randomized into two groups, one receiving Zoledronate alone and the other receiving Zoledronate together with low-dose IL-2 subcutaneously (s.c.).

Pressey et al.	2016	Neuroblastoma	Zoledronate + IL-2	(65)

MM, multiple myeloma; NHL, non-Hodgkin lymphoma; FBCL, follicular B-cell lymphoma; RCC, renal cell cancer; AML, acute myeloid leukemia; BrHPP, bromohydrin pyrophosphate; IL, interleukin.

The treatments were well tolerated and a significant clinical response was observed in the group receiving Zoledronate and IL-2 during the 1-year follow-up, which correlated with sustained elevated numbers of blood V γ 9V δ 2 T_{EM} cells producing IFN- γ and TRAIL.

We also conducted a phase I trial in 10 advanced metastatic breast cancer patients, using the same Zoledronate and IL-2 regimen as in the above study (60), and found that 3 patients who sustained V γ 9V δ 2 T cell numbers achieved either disease stabilization (2 patients) or partial remission (1 patient).

While the above studies by the Wilhelm's group and our group have used n-BPs and IL-2, Bennouna and colleagues (61) conducted a phase I trial using the synthetic PAg BrHPP with low doses of IL-2 in 28 patients with solid tumors. Patients first received BrHPP alone intravenously (i.v.) and then were treated with BrHPP i.v. in combination with IL-2 s.c. at weekly intervals. The BrHPP and IL-2 treatment was well tolerated and induced *in vivo* dose-dependent V γ 9V δ 2 T cell amplification. Based on these findings and the results from a preclinical study in macaques (62), Bennouna and colleagues conducted a multicentric phase II trial with BrHPP and IL-2 in 45 patients with follicular B-cell lymphoma who had been previously treated with the anti-CD20 mAb Rituximab. The treatment provoked expansion of V γ 9V δ 2 T lymphocytes in 39 out of the 45 patients, which peaked 1 week after the first injection of BrHPP, but declined upon subsequent injections. However, V γ 9V δ 2 T cells acquired the capability to produce IFN- γ and TNF- α and expressed Fc γ RIII (CD16) which promoted ADCC activity after the second and third injections of BrHPP. Clinical results from 38 patients consisted of 10 instances of complete remission (CR) and 17 overall response rate. Therefore, administration of BrHPP, IL-2 and Rituximab produced very promising results, with limited side effects, overall supporting the potential of combining V γ 9V δ 2 T cell-based therapies with mAbs.

In contrast with these extremely promising results, two other phase I trials have confirmed that the V γ 9V δ 2 T cell-based therapy is well tolerated, but have not shown evidence of anti-tumor effects. Lang and colleagues (63) have conducted a phase I trial with Zoledronate and IL-2 in 12 patients with metastatic renal cell carcinoma. All patients experienced low grade adverse events, but no clinical response was observed. Rather, the treatment induced a significant decrease of the *in vitro* V γ 9V δ 2 T cell proliferative response in the majority of the patients.

In another study, Kunzmann and coworkers (64) conducted a prospective phase I study with Zoledronate and IL-2 in 21 patients with different advanced malignancies. The regimen was well tolerated and caused a marked *in vivo* activation and IFN- γ production of V γ 9V δ 2 T cells in all evaluable patients, but objective responses (partial remission) were observed only in two patients with acute myeloid leukemia. Interestingly, the lack of clinical response was associated with elevated pretreatment levels of serum vascular endothelial growth factor, which were even increased upon injection of Zoledronate and IL-2.

Finally, a recent prospective, non-randomized Phase I trial, has been conducted in nine young patients with refractory neuroblastoma, which has demonstrated that *in vivo* administration of Zoledronate and IL-2 s.c. can safely expand *in vivo* circulating

V γ 9V δ 2 T cells, suggesting that intentional *in vivo* activation of V γ 9V δ 2 T cells might represent a strategy for the treatment of neuroblastoma (65).

RESULTS FROM CLINICAL TRIALS BASED ON ADOPTIVE TRANSFER OF *EX VIVO*-EXPANDED $\gamma\delta$ T CELLS

Phase I clinical trials using adoptive transfer of *ex vivo*-expanded $\gamma\delta$ T cells have yielded somewhat conflicting results. A survey of these studies in different types of cancer is shown in **Table 2**.

Five studies have given results suggesting an antitumor effect of the therapy. Two trials were carried out by Kobayashi's group in patients with advanced renal cell carcinomas; in one study (66), seven patients received Zoledronate-expanded V γ 9V δ 2 T cells and IL-2 i.v. All patients had mild adverse events, four patients showed a significant *in vivo* expansion and IFN- γ production by V γ 9V δ 2 T cells, but the clinical benefit was moderate, as only three out of seven patients showed delayed tumor doubling time (66). In the second trial from the same group, all 11 patients receiving Zoledronate-expanded V γ 9V δ 2 T cells and IL-2 showed prolonged tumor doubling time (67).

In another trial Nicol and coworkers (68) evaluated the safety and feasibility of the adoptive transfer of V γ 9V δ 2 T cells expanded *ex vivo* with Zoledronate and IL-2, in combination with Zoledronate given i.v. to 18 patients with advanced solid tumors who continued their previously ineffective chemotherapy. No toxicity was reported, and 3 out of the 18 patients had clinical responses (68). Interestingly, authors tracked V γ 9V δ 2 T cells labeled with ¹¹¹In in three patients. The cells localized to the lungs and remained there for 4–7 h after injection and then migrated to the liver and spleen. In one patient with a large metastasis in the left adrenal gland, the cells accumulated in the metastatic site 1 h after injection and remained there until 48 h.

In a fourth trial, four patients with advanced hematological malignancies received haploidentical transplants (69) highly enriched for V γ 9V δ 2 T cells, followed by *in vivo* administration of Zoledronate and IL-2. Three patients showed CR during the

TABLE 2 | Survey of clinical trials based on adoptive transfer of *ex vivo*-expanded $\gamma\delta$ cells.

Nakajima et al.	2010	NSCLC	V γ 9V δ 2 + Zoledronate + IL-2	(73)
Sakamoto et al.	2011	NSCLC	V γ 9V δ 2 + Zoledronate + IL-2	(74)

MM, multiple myeloma; RCC, renal cell cancer; NSCLC, non-small cell lung cancer; BrHPP, bromohydrin pyrophosphate; IL, interleukin.

6-month follow-up, while one patient died of an infection 6 weeks after the cell transfusion.

Most recently, Wada and coworkers have conducted a pilot study in seven patients with neoplastic ascites caused by gastric cancer with V γ 9V δ 2 T cells expanded *ex vivo* with Zoledronate and IL-2, administered together with Zoledronate i.v. Weekly Intraperitoneal injection of V γ 9V δ 2 T cells had no severe adverse events and caused a significant reduction of the number of tumor cells in the ascites, which was evident soon after the first cycle of therapy and sustained over time. CT scan also revealed a significant reduction in volume of ascites in two out of the seven patients. Authors conclude that injection of V γ 9V δ 2 T cells can result in the control of malignant ascites in patients for whom no standard therapy is available (70).

In contrast to the above successful studies, several other phase I trials, while showing that V γ 9V δ 2 T cell adoptive therapy is well tolerated, failed to providing evidence of antitumor effects.

Abe et al. (71) conducted a trial in six subjects with MM who received Zoledronate-expanded V γ 9V δ 2 T cells in combination with Zoledronate and IL-2. The treatment was safe but clinical efficacy, as assessed by M-protein serum levels remained at baseline in four patients and increased in two patients, in the absence of between the number of V γ 9V δ 2 T cells injected and clinical outcome.

Bennouna et al. (72) conducted a phase I trial using *ex vivo*-expanded V γ 9V δ 2 T cells in combination with BrHPP and IL-2, in 10 patients with metastatic renal cell carcinoma. Overall, the therapy was well tolerated with only one severe effect, 6 out of 10 patients showed stable disease, but there was no significant antitumor effect.

Finally, in 2 studies of non-small cell lung cancer (NSCLC) involving 10 and 15 patients, respectively (73, 74), who received *ex vivo*-expanded V γ 9V δ 2 T cells and IL-2, there were no objective clinical responses although about one-third to one-half of the patients showed stable disease after therapy. In one study, Nakajima and coworkers (73) treated 10 patients with NSCLC with V γ 9V δ 2 T cells expanded *ex vivo* with Zoledronate and IL-2. The treatment was safe, three patients showed stable disease and five patients showed a progression of the disease 4 weeks after the last treatment. In the other study, Sakamoto and coworkers (74) injected *ex vivo*-expanded $\gamma\delta$ T cells in patients with advanced NSCLC. Fifteen patients undergoing treatment with these $\gamma\delta$ T cells did not have severe adverse events, all patients remained alive during the study period, but there were no objective responses.

WHAT DO THE $\gamma\delta$ T CELL-BASED CLINICAL TRIALS TEACH US?

Clinical trials exploiting $\gamma\delta$ T cells in cancer have been conducted over the past decade, with a good safety profile but variable efficacy. What is clear from these studies is that there is enormous variation in the types of cancer treated, combined with heterogeneity in the protocols used to expand $\gamma\delta$ T cells *in vivo* or *ex vivo* for cellular immunotherapy, or in how the immunotherapy was delivered (e.g., PAgS or Zoledronate with

or without IL-2, or in combination with other drugs, $\gamma\delta$ T cells alone or in combination with activating drugs such as IL-2 and Zoledronate). In addition, several factors may influence the success of $\gamma\delta$ T cell-based immunotherapy, which will be discussed in this section.

Immunotherapy strategy based on intentional activation of V γ 9V δ 2 T cells *in vivo* by administration of PAgS or n-BPs and IL-2 has been effective in activating circulating V γ 9V δ 2 T cells, but there is no evidence that this approach reaches tissue-resident $\gamma\delta$ T cells or even promotes their recruitment at the tumor site, where they should in fact exert their antitumor activities.

Moreover, patients with several types of tumors have low numbers and unresponsive $\gamma\delta$ T cells (75), even if more recent evidences indicate that reductions of $\gamma\delta$ T cell numbers and functions might be associated with age and sex and not with the presence of the tumor (76–78).

In addition, a decreased number of circulating V γ 9V δ 2 T cells have been observed as injections of PAgS or Zoledronate and IL-2 progressed, which was accompanied by a lower response of peripheral blood V γ 9V δ 2 T cells to PAgS.

The precise mechanism underlying this phenomenon remains unknown and further investigations are thus necessary. Among the possibilities, activation-induced V γ 9V δ 2 T cell anergy has been frequently reported (75), possibly due to inadequate signals delivered during activation, exposure to suboptimal PAgS concentration or from V γ 9V δ 2 T cell intrinsic features.

A recent clinical trial of Zoledronate given i.v. to cancer-free patients showed that the inflammatory-type side effect of Zoledronate (flu-like syndrome) could be easily predicted by analyzing *in vitro* production of IFN- γ by Zoledronate-stimulated peripheral blood mononuclear cells (79). In agreement with these data, we and others have shown that repeated i.v. injections of Zoledronate was accompanied by decrease of circulating V γ 9V δ 2 T_{CM} cells and reduction of their proliferative responses *in vitro* (79, 80). Circulating neutrophils may also contribute as they take up Zoledronate and produce hydrogen peroxide that inhibits T cell proliferation (81). Finally, repeated stimulation of V γ 9V δ 2 T cells may also cause terminal differentiation and exhaustion (82–84).

Immuno-evasion strategies can be exploited by cancer cells to escape recognition and attack by V γ 9V δ 2 T cells. Indeed, several evidences demonstrate that cancer cells acquire the capability to inhibit immunological checkpoints using several different strategies. However, a very recent study has shown that V γ 9V δ 2 T cells express very low programmed death-1 (PD-1) compared with conventional $\alpha\beta$ CD8 and CD4 T cells, which was markedly up-regulated over the first 4 days of exposure to Zoledronate and IL-2 *in vitro* but by day 7 dropped nearly to baseline (85). While these results suggest that V γ 9V δ 2 T cells may circumvent the PD-1/PD-1L checkpoint *in vivo*, Hayday and coworkers found that V γ 9V δ 2 T cells express another negative checkpoint receptor, TIGIT, upon *in vitro* activation, thus providing an additional opportunity to cancer cells to escape V γ 9V δ 2 T cell-mediated elimination (Hayday, unpublished results). Evasion strategies that specifically impair V γ 9V δ 2 T cell functions can involve diverse immunosuppressive mediators produced in the tumor microenvironment, as, for example,

transforming growth factor- β , prostaglandins, kynurenins, or potassium (86–89).

All of the above pitfalls may be partly overcome by utilization of the adoptive cell transfer of *ex vivo*-expanded V γ 9V δ 2 T cells, which thus seems to be a more effective procedure. However, the problem appears to be how to sustain the levels and functions of the transferred V γ 9V δ 2 T cells. In metastatic renal cell carcinoma, two groups reported superior efficacy when V γ 9V δ 2 T cells were administered with Zoledronate and/or IL-2, as compared to V γ 9V δ 2 T cells administered alone (67, 90).

While the aforementioned trials utilized patients' autologous peripheral blood-derived V γ 9V δ 2 T cells, a recent study by Wilhelm and colleagues (69) utilized V γ 9V δ 2 T cells from haploidentical donors; this treatment did not cause graft-versus-host disease and was clinically effective as three out of four patients achieved CR (69). V γ 9V δ 2 T cells from the haploidentical donor persisted for 28 days and expanded *in vivo* following injection of Zoledronate and IL-2.

Other studies have shown that it is possible to sustain injected V γ 9V δ 2 T cells without IL-2 supplementation, probably relying on IL-15 (91) or on IL-18 (92, 93) spontaneously produced by the host.

CAN WE IMPROVE $\gamma\delta$ T CELL-BASED TUMOR IMMUNOTHERAPY?

$\gamma\delta$ T cells can be redirected to the cancer cell using antibodies (Figure 2). This can be achieved, for instance, by using bispecific antibodies, in which one binding site recognizes a tumor-specific cell surface molecule (for example, EpCAM or HER2/neu) and the other binding site targets CD3 or the V γ 9 chain of the V γ 9V δ 2 TCR; such bispecific antibodies have been demonstrated effective in preclinical models (94, 95).

As a variant of the bispecific antibody technology, Zheng et al. (96) prepared a chimeric molecule in which the variable portion derived from the extracellular domains of a V γ 9V δ 2 TCR (cloned from a V γ 9V δ 2 T cell infiltrating ovarian cancer) and the constant region was the fragment crystallizable (Fc) domain of human IgG1. This chimeric construct bound to several ovarian cancer cells, recognizing a yet unknown antigen and promoted the killing of the cells *via* ADCC mediated by binding of the Fc region of the chimeric construct to CD16.

Wesch and colleagues (97) developed recombinant immunoligands consisting of a CD20 single-chain variable fragment (scFv) linked to MICA or ULBP2 and found that both constructs

promoted the cytotoxic activity of *ex vivo*-expanded $\gamma\delta$ T cells (containing both V δ 1 and V δ 2 T cells) against CD20-positive lymphoma cells. Importantly, these two immunoligands mediated the killing of chronic lymphocytic leukemia cells isolated from patients by $\gamma\delta$ T cells, which was even enhanced by the PAG BrHPP. Thus, the utilization of recombinant immunoligands which engage NKG2D, with or without simultaneous TCR triggering, may represent an attractive strategy to enhance antitumor cytotoxicity of $\gamma\delta$ T cells.

Another approach consists in lentiviral-mediated transduction of T cells with chimeric antigen receptors (CARs; **Figure 2**). CARs are usually derived from scFvs of antibodies specific for tumor antigens, thus enabling the CAR-transduced T cells to recognize tumor epitopes independently on their TCR [reviewed in Ref. (98)].

To date, most CAR utilize $\alpha\beta$ T cells, but $\gamma\delta$ T cells are also an appealing target, due to their antitumor effector functions.

Deniger et al. (99) have transduced polyclonal $\gamma\delta$ T cells with a CD19-specific CAR which conferred the capability to efficiently kill CD19⁺ leukemia cells. The CAR technology has been combined with the generation of induced pluripotent stem cells from human peripheral blood T cells (100). Such cells showed a very similar phenotype to $\gamma\delta$ T cells and exerted antitumor activity.

T cells can be redirected to tumors by lentiviral-mediated transduction with an exogenous TCR of known anticancer specificity, following adoptive transfer into patients. Typically, the vast majority of studies have involved transduction of an $\alpha\beta$ TCR of well known antitumor specificity into another $\alpha\beta$ T cell (101). The major problem with this strategy is the risk of mispairing between the endogenous and exogenous TCR α and β chains, resulting in receptors with autoreactive specificities (102, 103). $\gamma\delta$ T cells offer an attractive solution to this problem, in the sense that a given tumor-specific $\alpha\beta$ TCR can be introduced into $\gamma\delta$ T cells without the risk of mispairing (104, 105). Another advantage is that $\gamma\delta$ T cells transduced with an $\alpha\beta$ TCR retain the functionality of their original TCR, thereby responding rapidly upon antigen stimulation (106).

The main obstacle associated with the $\alpha\beta$ TCR transfer, is that $\gamma\delta$ T cells do not express CD4 or CD8 co-receptors, which are required for efficient recognition of peptide–MHC complexes on target cells. This implies that co-transduction with a co-receptor (107) or use of very high affinity TCRs (108) would be desirable

to enhance antitumor activity of $\alpha\beta$ -transduced $\gamma\delta$ T cells. It is also possible to transduce peripheral lymphocytes (both $\gamma\delta$ and $\alpha\beta$) with a specific $\gamma\delta$ TCR, as successfully demonstrated by Zhao and coworkers (109, 110).

Finally all $\gamma\delta$ T cell-based clinical trials in patients with hematologic and solid tumors have relied on the utilization of V γ 9V δ 2 T cells. V δ 1 T cells are typically less susceptible to activation-induced exhaustion and in theory could persist long after adoptive transfer, providing the host with a durable antitumor immune response (111). Moreover, as V δ 1 T cells express several NK receptors and possess a highly cytotoxic potential (8), they may constitute a potent therapeutic lymphocyte population that could be exploited in alternative to, or in addition to V γ 9V δ 2 T cells. Accordingly, Silva Santos and coworkers (112) have recently developed a clinical-grade method to selectively expand V δ 1 T cells. The expanded V δ 1 T cells efficiently inhibited tumor growth and prevented dissemination in xenograft models of leukemia, thus providing a preclinical proof of principle for application of V δ 1 T cells in adoptive immunotherapy of cancer.

CONCLUSION

Overall, studies performed to date have clearly demonstrated that $\gamma\delta$ T cell-based tumor immunotherapy is safe, but clinical performance has been inconsistent (31). Identification of the ligands recognized by V δ 1⁺ and V δ 2⁺ T cells, the antigen and cytokine requirements for their differentiation and survival, and the interactions they establish with tumor cells and other different components of the tumor microenvironment, will lead to a better understanding of how $\gamma\delta$ T cells work and to properly harness these cells for effective and durable tumor immunotherapy.

AUTHOR CONTRIBUTIONS

EG, GC, and GG provided clinical samples and patient's data. EP and GP analyzed data in the literature and prepared figures. FD and SM wrote the manuscript.

FUNDING

This work was supported by grants from the Ministry of Health “Ricerca Finalizzata 2007” (to FD) and the University of Palermo.
