For the razor clam Solen grandis, siphonal autotomy and regeneration is a necessary means of facing external stress, which is accompanied by a large amount of energy consumption. To explore the function of the ENO4 gene in the siphonal autotomy and regeneration of S. grandis, the full-length cDNA of the ENO4 in S. grandis was cloned and characterized. The full-length cDNA of SgENO4 was 2,773 base pairs (bp), with an 1,851 bp coding sequence (CDS) encoding 616 amino acids. Bioinformatic analysis revealed a slightly lower codon usage bias and a relatively stable nucleotide composition in the SqENO4 sequence. Three conserved motifs were found from the SqENO4 sequence. These conserved motifs vary in length from 14 to 27 amino acids. Moreover, in the siphonal pre-autotomy of razor clams, expression level of the SgENO4 gene was significantly higher in the hepatopancreas and siphonal base than other tissues (P < 0.05). However, the expression of the SgENO4 gene in the siphonal base decreased significantly in the siphonal post-autotomy 7 hours and gradually recovered as the regeneration process continued. Linear correlation analysis showed that there was a significant linear correlation between specific weight of siphon and relative expression levels of SqENO4 ($R^2 = 0.826$). RNA interference (RNAi) result showed that the specific weight (the proportion of siphonal weight to body weight) is significantly lower than other groups on the seventh day (P <0.05), suggesting that interfering with the expression of the SgENO4 gene could inhibit the siphonal regeneration of S. grandis. These results further demonstrate that SqENO4 is a conserved sequence and that it plays a crucial role in the siphonal autotomy and regeneration of S. grandis, advancing further understanding in exploring molecular mechanisms in the siphonal autotomy and regeneration.

KEYWORDS

Solen grandis, SgENO4 gene, regeneration, siphon, autotomy

1 Introduction

Solen grandis, commonly known as the razor clam, inhabits the intertidal zone at depths of 20 - 40 cm and is naturally distributed along the west coast of the Pacific Ocean (Yuan et al., 2010). In the Chinese seafood market, S. grandis is one of the most expensive (100 CNY/kg) shellfish because of its rich and flavorful meat (Yuan et al., 2012). However, during aquaculture, transport and sales, S. grandis is highly sensitive to external stimuli such as tides and the agitation of symbiotic organisms, collisions, and shaking, causing the razor clam siphon to be prone to autotomy (Wu et al., 2022b). Similar to spiders, geckos, and crabs, S. grandis is able to perform autotomy of its appendage (siphon) and hence, it avoids being preyed (Mykles, 2001; Wrinn and Uetz, 2007; Kaczmarski et al., 2020; Wu et al., 2022b). After siphonal autotomy, razor clams are weak and may even die, unable to dive deep into the sand, which has serious effects on survival, feeding, and digestion (Wu et al., 2022b). Fortunately, autotomized appendages may be replaced by regeneration in S. grandis.

Regeneration is a process in which the whole or organ of an organism is damaged by external forces and part of it is lost, and on the basis of the remaining part, a structure identical in form and function to the lost part is grown (Barr et al., 2020). The ability of siphonal regeneration in clams may be due to the successful wound healing (Wang et al., 2021). Wound healing is necessarily accompanied by stress, immunity and cell proliferation, which need consume a large amount of energy (Wang et al., 2021). Although some progresses have been made in these areas, the mechanism of regeneration in mollusks remains largely unclear (Bely et al., 2014).

As the rate-limiting enzyme in the glycolysis process, enolase can catalyze the conversion of glycerol phosphate (PGA) to phosphoenolpyruvate (PEP), and can also catalyze its reverse reaction process (Feo et al., 2000; Sun et al., 2022). As a result, enolases play an important role in the energy metabolism of cells. Once, enolase has long been regarded as a single functional and evolutionarily conserved ancient enzyme (Straeten et al., 1991). However, A growing body of research has demonstrated that enolase belongs to a new family of proteins called part-time functional proteins, which have a variety of functions related to cell pathophysiology and other activities, such as involvement in cell apoptosis, inflammatory responses and bacterial infection (Yu et al., 2012; Luo et al., 2021). For instance, enolase gene is a key gene related to the growth of Litopenaeus vannamei (Li et al., 2011). The expression and distribution of enolase in Helicoverpa armigera is related to the pathological environment of the cell and the degree of vigorous metabolism. Enolase may play a role in the body's energy sources in life activities such as worm growth and development and nutrient metabolism (Hu, 2017). Regeneration, therefore, as a particular form of growth, and we doubt whether enolase plays any role in the siphonal regeneration of S. grandis. But to the best of our knowledge, no studies have investigated the molecular properties and function of enolase in S. grandis.

In this study, we investigated the *ENO4* gene in *S. grandis* by cloning its full-length cDNAs and examining its expression levels during siphonal autotomy and regeneration in adult tissue. Then, we compared siphonal growth rate (weight) and gene expression levels of the clam under developmental stage of siphon. The results of this study will improve our understanding of the function of

SgENO4 and the mechanism of siphonal regeneration, and can better guide aquaculture efforts for *S. grandis*.

2 Materials and methodology

2.1 Experimental design and samples collection

The razor clams *S. grandis* were collected from the Jiangsu fine breeding farm of *Solen grandis* (Nantong, China). Adult clams (2-year age) were selected in July with shell length of 105.62 ± 2.60 mm for following experiments. Before the experiment, all the razor clams were temporarily kept in the tank for two days at a salinity of $22\sim23\%$, a pH of 8.1-8.3, and a temperature of $26\sim29^{\circ}$ C.

2.2 Total RNA isolation, cDNA synthesis and full-length cloning of the *sgENO4* gene

Analytical methods for total RNA isolation, cDNA synthesis, and full-length cloning referred to the methods published in previous studies (Chen et al., 2017; Wu et al., 2022a). The 5' RACE and 3 'RACE specific primers were designed on the known intermediate fragments (Table 1). Real-time fluorescent quantitative PCR was used to analyze the expression levels of *SgENO4* gene (Applied Biosystems, USA). The amplification system was configured according to the instruction of Tiangen fluorescence quantitative premix kit eferred to the methods published in previous studies. The β -actin gene was used as an internal control gene (Table 1). Dissociation curves of amplified products were analyzed at the end of each PCR analysis (Chen et al., 2017; Wu et al., 2022a).

2.3 Bioinformatic analysis of *SgENO4* gene sequence

After the sequence splicing, the sequence analysis was performed with slight modifications as published in previous studies (Chen S. et al., 2017; Wu et al., 2022a; Yan et al., 2022; Zhang et al., 2022). Multiple expectation maximization for motif elicitation (MEME) program in TBtools software (version 1.09) was used to analyze the conserved motifs of the *ENO4* genes (Chen et al., 2020; Yu et al., 2022). Nucleotide composition and synonymous codons were analyzed using Codon W software (version 1.4.2) (Chen Y. et al., 2017; Hou, 2020).

2.4 Expression of *SgENO4* gene during siphonal autotomy and regeneration

Additionally, a total of 80 razor clams were kept in four polyethylene tanks (diameter = 100 cm, height 80 cm, each), and then induced to remove siphons. Prior to culture trials, all prepared

TABLE 1 Primers of sequence used.

Primer name	Sequence (5′→3)	Description
SgENO4 5'-RACE	GGCTGCCAGTACATTCTCGT	5' RACE

dsSgENO4-NCR:	TAATACGACTCACTATAGGGTATGCAATGACAACCCCTTCTGA	RNAi

aquariums were cleaned, filled with sand-filtered seawater, and laid with 20 cm thick soil. During the rearing period, clam diet was established utilizing a mixture of three microalgae (50 *Isochrysis galbana* cell per μ L, 25 *Pavlova lutheri* cell per μ L and 25 *Chaetoceros calcitrans* cell per μ L) twice a day (Trigos et al., 2018). The rearing water was changed regularly and removed dead individuals in a timely manner. Five razor clams were randomly selected to measure live body weight and siphonal weight in pre-autotomy, 7h, 7d, 14d and 21d after autotomy, respectively, and the liver, gill, foot, gonad and siphonal base tissues were dissected into sterile tubes, respectively(1.5mL). Each sample was washed with 0.01 M phosphate buffered saline, immediately frozen in liquid nitrogen, and stored at -80°C until and qRT-PCR.

2.5 RNAi

Razor clams were removed siphon and reared in the polyethylene tanks (blank control group). 0.9 mL depc-water was injected into the siphonal roots of *S. grandis* by micro syringe (depc-water control group). Similarly, 0.9 mL depc-water with 1 μ g *dsSgENO4* (experimental group) and nonsense *dsSgENO4* (negative control group) were injected into the siphonal base of *S. grandis*, respectively. After successful injection, three randomly selected razor clams were taken on days 1, 3, 7, and 10 to record and assay siphonal weight and relative expression levels of *SgENO4*.

2.6 Statistical analysis

The relative copy number of fluorescence quantitative data was calculated according to $2^{-\Delta\Delta Ct}$ (Livak and Schmittgen, 2002). In order to detect statistically significant differences, all quantitative data were subjected to ANOVA after homogeneity and normality tests using SPSS software (version 20.0). It was used to determine significant differences among means (P < 0.05) by Duncan' s multiple range test.

3 Results

3.1 Characterization of SgENO4 gene

The full-length cDNA sequence of *SgENO4* gene was cloned using RACE. *SgENO4* was 2,773 bp long (Genbank accession number: ON526756.1), which consist of a 244 bp 5'- untranslated region (UTR), a 678 bp 3'- untranslated region (UTR) and an 1,851 bp coding sequence (CDS). The CDS encoded 616 amino acids with a predicted molecular weight and theoretical pI of 117.47 kDa and 5.03, respectively. The SMART program results showed that *SgENO4* gene possessed N-terminal and C- terminal TIM bucket domain of enolase (Figure 1). The predicted secondary and tertiary structures of the SgENO4 protein is shown in Figures 2A, B. SgENO4 protein consisted of 22 α -helixes; 13 β -strands; and 34 coils, respectively.

3.2 Characterization of codon usage pattern in the *SgENO4* gene

Nucleotide composition analysis revealed that SgENO4 had the highest compositional value of U% (31.66), which was followed by A% (25.50) and C% (24.16), the lowest compositional value of G% (18.68). It appears that there may be more usage bias of U nucleotides among SgENO4 codons. At the third codon position (A3, U3, G3, C3, GC3), C3% (36.58) was the highest, followed by U3% (32.46), and similar A3% (30.64) and G3% (29.15). Interestingly, mostly over-represented and underrepresented codons are C-ended and G-ended, respectively, which also reveals that the preferred codons are influenced by compositional constraints. However, GC% and GC3% composition is 49.0% and 50.1%, respectively, suggesting that there is slightly lower codons usage bias in the SgENO4 sequence.

To explore the extent of the codons usage bias, the relative synonymous codon usage (RSCU) values of the overall 64 codons, including 59 sense codons, 3 termination codons (TER) and 2 no-bias codons (AUG and UGG), were calculated (Figure 2C). The results

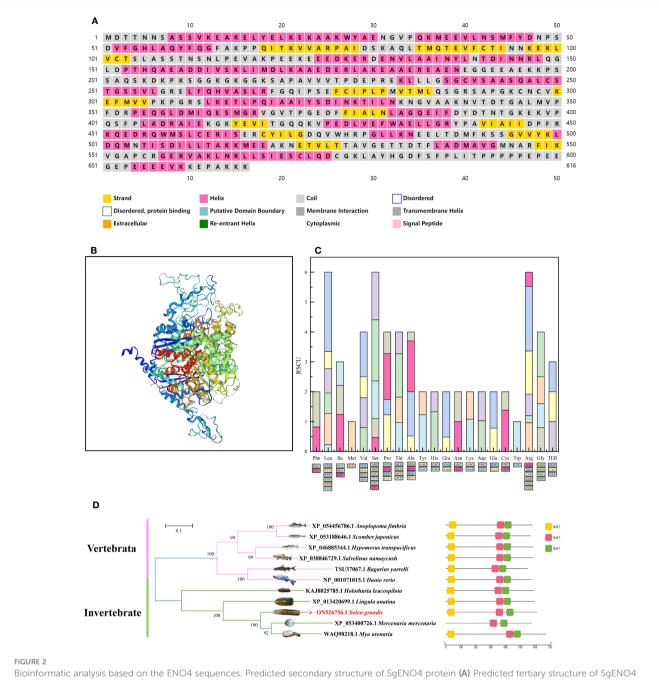

FIGURE 1

Nucleotide and predicted protein sequence of SgENO4. The uppercase letters in cDNA represent the coding sequence (CDS), and the lowercase letters represent the 5' and 3' noncoding regions. The start (ATG) and stop (TGA) codons are presented in the red box. The blue box represents the N-terminal domain of enolase, and the green box represents the C-terminal TIM bucket domain.

showed that the most frequently used codon is GAG (Glu, 39 times), and the least frequently used codon is UCG (Ser, 0 times). Among the 23 most abundantly used codons (RSCU >1), 10 codons are G/C-ended and 13 codons are A/U-ended, which evidently confirmed that there exists low codon usage bias in the *SgENO4* sequence. Furthermore, the effective number of codons (ENC) was also used to quantify the absolute codon usage bias of *SgENO4* sequence. The value of ENC is 54.36, which reveals a relatively stable nucleotide composition and slightly lower (ENC>40) codon usage bias.

The predicted SgENO4 protein shares a sequence identity with *Mya arenaria* (54.66% similarity), *Mercenaria mercenaria* (52.47% similarity), *Lingula anatina* (50.51% similarity)

(Figure 3). A phylogenetic tree was formed using ENO4 protein sequences and other species (Figure 2D). The phylogenetic tree presents that SgENO4 have a close evolutionary relationship with *Mya arenaria, Mercenaria mercenaria* and *Lingula anatina*, while are far away from vertebrate ENO4 members, providing firm phylogenetic evidence for the identities of the *Solen grandis* ENO4 gene. Then, all motifs were identified by the MEME database with complete amino acid sequence of ENO4. The differentiation of the ENO4 protein across species is not obvious, and three conserved motifs were found (Figure 2D). The length of these conserved motifs varied from 14 to 27 amino acids (Table 2).

protein (B) Codon distribution in SgENO4 (C) motif analysis of ENO4 (D). All motifs were identified by the MEME database with complete amino acid sequence of ENO4. Lengths of motifs for each ENO4 protein are displayed proportionally.

3.3 The expression of *SgENO4* in different tissues and siphonal autotomy and regeneration stages

Our results indicate that *SgENO4* is ubiquitously expressed in all tissues and stages of siphonal autotomy and regeneration (Figure 4). The relative expression level of *SgENO4* in the hepatopancreas is higher than other tissues in the stage of siphonal pre-autotomy, followed by siphonal base (P<0.05). However, the expression levels of *SgENO4* in the gill, gonad, and foot are low. Moreover, with tissue regeneration in the siphonal post-autotomy, the relative expression level of *SgENO4* in

the siphonal base gradually increases to the maximum (on the 21st day) and is significantly higher than that in other tissues (P<0.05).

3.4 Relationship between siphonal regeneration and relative expression levels *SgENO4*

As presented in Table 3, the siphon can regenerate to the preautotomy status about 21 days after siphonal autotomy of razor clam. On the 21^{st} day, the siphonal weight of *S. grandis* accounted

for 9.25% of the live body weight. It is noted that the relative expression levels of *SgENO4* was consistent with the trend of specific weight of siphon (Figure 5A). Therefore, Linear regression models were simultaneously constructed with specific weight as the *x*-axis and relative expression levels of *SgENO4* as the

y-axis. The result showed that there was a significant linear correlation between specific weight of siphon and relative expression levels of *SgENO4* ($R^2 = 0.826$, Figure 5B).

In order to verify the role of *SgENO4* gene in the siphonal regeneration of *Solen grandis*, the RNAi experiment was performed.

TABLE 2 List of the putative motifs in the SgENO4.

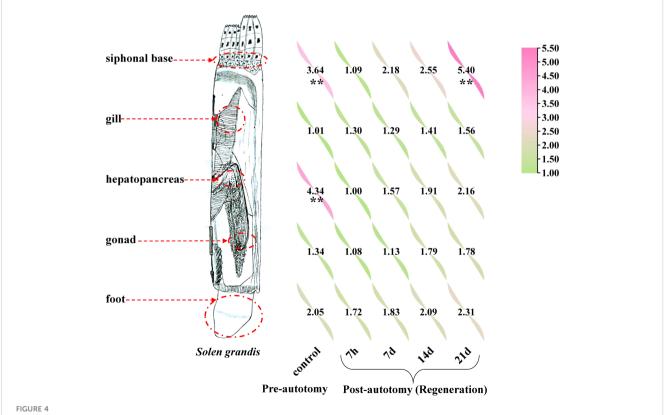

The results showed that the relative expression level of *SgENO4* first decreased and then increased and reached the lowest value on the seventh day, indicating that the expression of *SgENO4* was inhibited successfully (Figure 6A). The specific weight (the proportion of siphonal weight to body weight) is significantly lower than other groups on the seventh day (P < 0.05), suggesting that interfering with the expression of the *SgENO4* gene could inhibit the siphonal regeneration of *S. grandis* (Figure 6B).

4 Discussion

4.1 Characterization and bioinformatics analysis of the *SgENO4* gene products

The unique ENO4 transcript sequences were obtained by comparing the internal S. grandis transcriptome data (unpublished data) with NCBI database. Our study cloned enolase4 of S. grandis, namely SgENO4 gene. The molecular characteristics and the potential function in the siphonal autotomy and regeneration of S. grandis. The predicted amino acid sequence and tertiary structure of S. grandis are less similar to those of other species, which should not be considered as weakly conserved types. The main reason is that there is less information about the ENO4 gene in the existing database. In addition, SgENO4 gene possessed N-terminal and C-terminal TIM bucket domain of enolase. All motifs were identified by the MEME database with complete amino acid sequence of ENO4. The differentiation of the ENO4 protein across species is not obvious, and three conserved motifs were found. To gain further insight into the influence of nucleotide content in shaping the SgENO4 codon usage pattern, the nucleotide compositions were calculated. The results show that there is slightly lower codons usage bias in the SgENO4 sequence and the value of ENC is 54.36, which reveals a relatively stable nucleotide composition and slightly lower (ENC>40) codon usage bias. These results further demonstrate that ENO4 is a conserved ancient enzyme (Feo et al., 2000; Chen Y. et al., 2017; Hou, 2020).

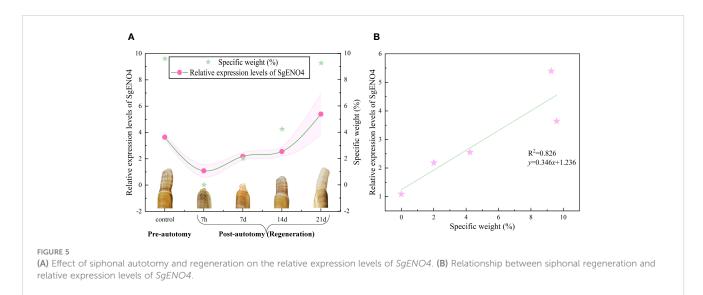

Relative expression levels of SgENO4 gene in different tissues and siphonal autotomy and regeneration stages. The asterisk (**) indicate a significant difference at P < 0.05.

TADLET	F (C) () () (
TABLE 3	Effect of siphonal	autotomy and	l regeneration of	n weight of razor clam.

Indicators	Pre-autotomy	Post-autotomy (regeneration)			
		7h	7d	14d	21d
Live body weight (g)	34.09 ± 1.34^{a}	33.39 ± 1.10^{a}	33.82 ± 1.30^{a}	34.13 ± 1.41^{a}	35.92 ± 0.36^{b}
Siphonal weight (g)	3.275 ± 0.52^{a}	-	$0.68\pm0.08^{\rm b}$	$1.45 \pm 0.13^{\circ}$	3.32 ± 0.43^{a}
Specific weight (%)	9.59	0.00	2.01	4.24	9.25

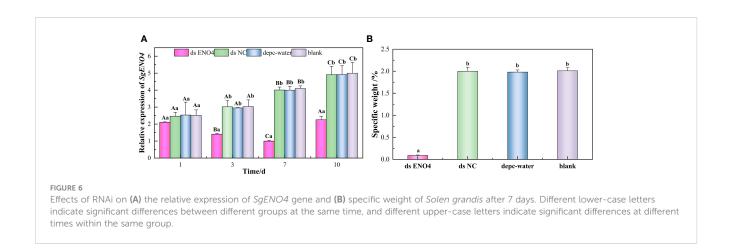

A different letter in a row indicates significant differences among groups (P < 0.05). Data are presented as mean \pm SD (n = 5).

4.2 Expression and function of *SgENO4* in siphonal autotomy and regeneration

As a key enzyme in glycolysis regulation, enolase indirectly drives mitochondria to produce large amounts of energy to sustain the organism's development and metabolism. The enolase gene has been confirmed to be highly expressed in a variety of cancer tissues and has become a potential biomarker of early-stage cancer, which is closely related to the proliferation and spread of cancer cells (Yu et al., 2012; Pan et al., 2020). Previous studies showed that the

expression and distribution of enolase in *Helicoverpa armigera* is related to the pathological environment of the cell and the degree of vigorous metabolism. Enolase may play a role in the body's energy sources in life activities such as worm growth and development and nutrient metabolism (Hu, 2017). In the present study, the *SgENO4* gene is expressed in all tissues, with significantly higher levels of expression in the hepatopancreas and siphonal base than in other tissues. This may be related to the fact that the hepatopancreas is a site of energy metabolism, and the siphonal recovery and regeneration requires a lot of energy. In addition, the high energy

requirements of the siphon, the filter feeding organ of razor clams, are also responsible for the high expression of the *SgENO4* gene (Luo et al., 2021; Zhang et al., 2022).

Enolase functions as a part-time protein with regional expression specificity and complex versatility. In addition to its role in energy metabolism during glycolysis, enolase plays an important role in tumor, immunity, infection, regeneration and other processes. many studies have shown that acute stress significantly affects energy metabolism processes in organisms and razor clam siphons are prone to autotomy because of external stimuli, such as tides and the agitation of symbiotic organisms (Wu et al., 2022b). Based on the expression patterns of oxidative phosphorylation related genes during liver regeneration in rats, previous study found that liver regeneration has stages, with gene expression levels decreasing in the early and middle stages of liver regeneration and gradually increasing in the middle and late stages (Lin et al., 2009). During tissue regeneration, enolase may participate in the recovery and regeneration of damaged tissue through the interaction of tubulin with microtubules (Keller et al., 2007; Sun et al., 2022). In the present study, the expression of the SgENO4 gene in the siphonal base decreased significantly within 7 hours of post-autopsy siphon base removal and gradually recovered as the regeneration process continued. This could also explain why razor clams are prone to die after low immunity. It has been speculated that the energy metabolism level of S. grandis drops sharply during the early stages of siphonal regeneration in response to wound. As the energy demand increases during regeneration, the energy metabolism level gradually increases to meet the wound healing and regeneration demand (Hu, 2017; Wang et al., 2021).
