Glaucoma is a group of disorders associated with retinal ganglion cell (RGC) degeneration and death. There is a clear contribution of mitochondrial dysfunction and oxidative stress toward glaucomatous RGC death. Mitochondrial uncoupling protein 2 (*Ucp2*) is a well-known regulator of oxidative stress that increases cell survival in acute models of oxidative damage. The impact of *Ucp2* on cell survival during sub-acute and chronic neurodegenerative conditions, however, is not yet clear. Herein, we test the hypothesis that increased *Ucp2* expression will improve RGC survival in a mouse model of glaucoma. We show that increasing RGC but not glial *Ucp2* expression in transgenic animals decreases glaucomatous RGC death, but also that the PPAR- $\gamma$  agonist rosiglitazone (RSG), an endogenous transcriptional activator of *Ucp2*, does not significantly alter RGC loss during glaucoma. Together, these data support a model whereby increased *Ucp2* expression mediates neuroprotection during a long-term oxidative stressor, but that transcriptional activation alone is insufficient to elicit a neuroprotective effect, motivating further research in to the post-transcriptional regulation of *Ucp2*.

**Keywords:** retina, RGC, *Ucp2*, glaucoma, neuroprotection, mitochondria, oxidative stress

## INTRODUCTION

Glaucoma is a group of disorders associated with retinal ganglion cell (RGC) degeneration and death (Quigley, 2011) and, after cataracts, is the most frequent cause of blindness worldwide (Resnikoff and Keys, 2012). An increase in intra-ocular pressure (IOP) is a prominent risk factor for glaucoma (Boland and Quigley, 2007), and most therapeutic solutions designed to prevent RGC death in glaucoma share the ability to decrease IOP. However, IOP reduction does not reduce glaucomatous visual field loss in roughly half of patients (Leske et al., 2004), necessitating development of adjuvant therapeutic modalities, including neuroprotective molecules that can protect RGCs.

The molecular mechanisms of glaucoma pathogenesis are multifactorial, but are frequently connected to an increase in damaging free radicals in the eye (Izzotti et al., 2003; Saccà and Izzotti, 2008), retina (Tezel et al., 2005), and optic nerve head (Malone and Hernandez, 2007; Feilchenfeld et al., 2008), herein termed oxidative stress. Ocular hypertension increases RGC oxidative stress (Chidlow et al., 2017), despite anti-oxidative support from endogenous antioxidant proteins (Munemasa et al., 2009) and resident glial cells of the retina, including astrocytes and müller glia (Varela and Hernandez, 1997; Carter-Dawson et al., 1998; Kawasaki et al., 2000; Woldemussie et al., 2004). Exogenous addition of serum antioxidants such as vitamin E is not necessarily protective from the disease (Ramdas et al., 2018), suggesting that current anti-oxidative therapeutics for glaucoma are insufficient. The early transcriptional responses of DBA2/J mouse RGCs to elevated IOP strongly suggest mitochondrial abnormalities in RGCs early in the disease (Williams et al., 2017), which appears to persist in multiple animal models (Coughlin et al., 2015; Takihara et al., 2015; Ito and Di Polo, 2017) as well as in human glaucoma (Abu-Amero et al., 2006; Piotrowska-Nowak et al., 2018).

Mitochondria are a well-known source of cellular free radicals, which during oxidative phosphorylation can leak from multi-protein complexes of the electron transport chain such as NADH:Ubiquinone Oxidoreductase and Coenzyme Q: Cytochrome C Oxidoreductase (St-Pierre et al., 2002). Mitochondrial ROS production is greater at hyperpolarized mitochondrial membrane potentials ( $\Psi_m$ ), and in isolated mitochondria small decreases in  $\Psi_m$  significantly decrease levels of ROS (Korshunov et al., 1997; Miwa et al., 2003). Endogenous uncoupling proteins, particularly the mitochondrial uncoupling protein 2 (UCP2), are able to protect nervous tissue from multiple sources of acute damage (Mattiasson et al., 2003; Andrews et al., 2005; Lapp et al., 2014; Barnstable et al., 2016) by decreasing  $\Psi_m$  and presumably ROS (Fleury et al., 1997; Eghtay et al., 2001). Lower levels of ROS are protective in most scenarios, but the predicted outcome of a lower  $\Psi_m$  is also a decreased mitochondrial drive for ATP synthesis (Klingenberg and Rottenberg, 1977). Therefore, it is unclear whether uncoupling proteins are beneficial for long-term neurodegenerative conditions. As with many neurodegenerative disorders, the clinical course of glaucoma progresses over multiple years. It is therefore essential that model systems of neurodegeneration develop over time and not in reaction to a single damaging insult.

In the microbead model of glaucoma, occlusion of the irido-corneal angle progressively increases damage to RGCs over a sub-acute time frame (Huang et al., 2018). Using this model, we tested whether enhanced *Ucp2* expression in mouse RGCs or in supporting glial cells is protective against injury. We found that increasing levels of *Ucp2* in RGCs, but not in GFAP-expressing glia, were neuroprotective. *Ucp2* levels are under several forms of transcriptional and translational control (Donadelli et al., 2014; Lapp et al., 2014), and our second goal was to determine whether factors that increase *Ucp2* transcription provide protection from cell death. We

found that the PPAR- $\gamma$  agonist rosiglitazone (RSG), a well-known transcriptional activator of *Ucp2*, does not alter RGC survival during glaucoma, implying an additional need to characterize clinically useful molecules which regulate *Ucp2* at post-transcriptional levels.

## MATERIALS AND METHODS

### Ethics Statement

This study was carried out in accordance with the National Research Council's Guide for the Care and Use of Laboratory Animals (8th edition). The protocol was approved by the Pennsylvania State University College of Medicine Institutional Animal Care and Use Committee.

### Animals

Wild-type (WT) C57BL/6/J and transgenic mice were housed in a room with an ambient temperature of 25°C, 30–70% humidity, a 12-h light–dark cycle, and *ad libitum* access to rodent chow. Transgenic mouse strains, B6.Cg-Tg(*GFAP-cre/ER<sup>T2</sup>*)505Fmv/J (*Gfap-creER<sup>T2</sup>*, Stock#: 012849) (Ganat et al., 2006) and Tg(*Thy1-cre/ER<sup>T2</sup>*, -EYFP)HGfng/PyngJ (*Thy1-creER<sup>T2</sup>*, Stock#: 012708) (Young et al., 2008), were each generated on a WT background and purchased from the Jackson Laboratory (Bar Harbor, ME, United States). *GFAP-creER<sup>T2</sup>* and *Thy1-creER<sup>T2</sup>* mice express a fusion product of *cre* recombinase and an estrogen receptor regulatory subunit (*creER<sup>T2</sup>*) under the control of the *hGFAP* or *Thy1* promoters, respectively. *CreER<sup>T2</sup>* activity is regulated by the estrogen receptor modulator and tamoxifen metabolite 4-hydroxytamoxifen (Zhang et al., 1996). *Ucp2KI<sup>fl/fl</sup>* mice were derived from *Ucp2KOKI<sup>fl/fl</sup>* mice (provided by Sabrina Diano, Ph.D.) and result from multiple back-crosses with WT mice (Toda et al., 2016). In these crosses, mice were selectively bred to retain the *Ucp2KI* sequence and the WT variant of the *Ucp2* gene. In these mice, a transgene was inserted in to the R26 locus, containing a *LoxP*-flanked stop codon followed by a copy of the mouse *Ucp2* cDNA and an IRES-EGFP sequence. Following cell-type specific cre-mediated excision of the *LoxP*-flanked stop codon, these mice express *Ucp2* and EGFP in astrocytes and müller glia (*Ucp2<sup>KI</sup>*; *GFAP-creER<sup>T2</sup>* mice) or in the vast majority of RGCs (*Ucp2<sup>KI</sup>*; *Thy1-creER<sup>T2</sup>* mice). To elicit cre-mediated excision of this stop codon, we injected mice intraperitoneally with 100 mg tamoxifen (Sigma, T5648)/kg mouse/day for 8 days, preceding any experimental manipulations. Same-litter cre recombinase-negative control mice (*Ucp2<sup>KI</sup>*) were also injected with tamoxifen to control for any potential biological impacts of tamoxifen.

Rosiglitazone was fed to WT mice by grinding 4 mg pills (Avandia, GSK) with a mortar and pestle and mixing them into ground normal mouse chow. We measured daily food consumption and adjusted the amount of RSG used based on food consumption. RSG was fed to mice beginning 2 days prior to microbead injection and does not alter IOP. During this study, we estimate an average RSG consumption of 28.2 mg RSG/kg mouse/day.

## Microbead Injection

We modeled glaucoma in mice by elevating IOP. We increased IOP in 2–4 month old mice of both genders as previously described (Cone et al., 2012). At least 24 h prior to bead injection, we took a baseline IOP measurement. Prior to bead injection, IOP is stable and is well represented by a single measurement. Immediately prior to bead injection, we anesthetized mouse corneas topically with proparacaine hydrochloride (0.5%) eyedrops and systemically with an intraperitoneal injection of 100 mg/kg ketamine/10 mg/kg xylazine. While anesthetized, we injected 6  $\mu\text{m}$  (2  $\mu\text{L}$  at  $3 \times 10^6$  beads/ $\mu\text{L}$ ; Polysciences, Cat#: 07312-5) and 1  $\mu\text{m}$  (2  $\mu\text{L}$  at  $1.5 \times 10^7$  beads/ $\mu\text{L}$ ; Polysciences, Cat#: 07310-15) polystyrene microbeads through a 50–100  $\mu\text{m}$  cannula in the cornea formed by a beveled glass micropipette connected by polyethylene tubing to a Hamilton syringe (Hamilton Company Reno, NV, United States). As an internal control, 4  $\mu\text{L}$  of sterile 1 $\times$  phosphate buffered saline (PBS) was injected in to the contralateral eye. We measured postoperative IOP every 3 days for 30 days. Following terminal IOP measurements, mice were asphyxiated using a Euthanex SmartBox system, which automatically controls CO<sub>2</sub> dispersion, followed by cervical dislocation.

## IOP Measurement

Intra-ocular pressure was measured in mice anesthetized by 1.5% isoflurane in air (v/v) using an Icare® TonoLab (Icare Finland Oy, Espoo, Finland) rebound tonometer, both before and after injection with polystyrene microbeads. Each reported measurement is the average of 18 technical replicates/mouse/eye. Mice were included in this study if their individual IOP was elevated by  $\geq 3$  mmHg or if a paired *t*-test of IOP over time between microbead and PBS-injected eyes was statistically significant ( $p < 0.05$ ). Baseline and bead-injected IOPs were compared between mouse strains to confirm the absence of any genotype-dependent differences in IOP increase.

## Histology and Immunocytochemistry

Immunolabeling of sectioned retinal tissue was performed as previously described (Pinzon-Guzman et al., 2011). Briefly, whole eyes were fixed in 4% paraformaldehyde (Electron Microscopy Sciences, Hatfield, PA, United States) in 1 $\times$  PBS overnight at 4°C. The next day, eyes were divided in half with a scalpel blade. One half was frozen and sectioned, while the other was labeled as a whole-mount. Frozen tissues were embedded in a 2:1 mixture of 20% sucrose and OCT (Electron Microscopy Sciences), cooled to  $-20^\circ\text{C}$ , and cut at a 10  $\mu\text{m}$  thickness. Samples for each experiment were located on the same slide to control for assay variability. Prior to immunohistochemical labeling, we unmasked antigens by exposing them to a 10 mM sodium citrate buffer (pH6.0) for 30 min at 100°C. Subsequent labeling of oxidative protein carbonyls was performed using an OxyIHC kit (EMD-Millipore, Cat#: S7450). Derivatization of protein carbonyl groups and all subsequent steps were performed in accordance with the manufacturer's instructions. Staining intensity was derived using the H-DAB vector of the ImageJ Color Deconvolution tool background was subtracted from each image, resulting in a numerical semiquantitative

measure of oxidative tissue stress. Tissue was imaged using an Olympus BX50 microscope. In this and all other experiments, the acquisition parameters for any given label were held constant.

Post-fixation, retinal whole mounts were permeabilized with 0.2% Triton-X-100 in PBS, blocked with 5% non-fat milk, and incubated in rabbit anti-RBPMS antibody (1:500, EMD Millipore) for 6 days at 4°C. Tissue was incubated in secondary antibody and 1  $\mu\text{g}/\text{mL}$  Hoechst-33258 overnight at 4°C prior to washing and mounting with 0.5% n-propyl gallate in 1:1 glycerol: PBS. Whole-mount tissue was imaged on a Fluoview FV1000 confocal microscope (Olympus).

## Retinal Ganglion Cell Counting

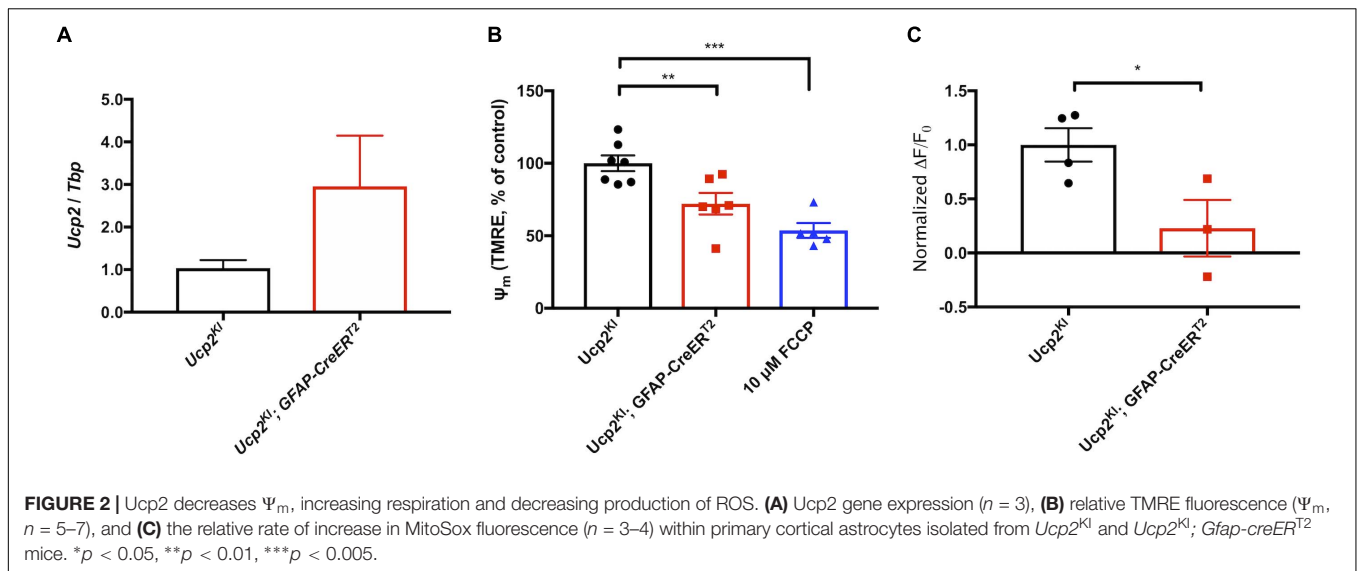

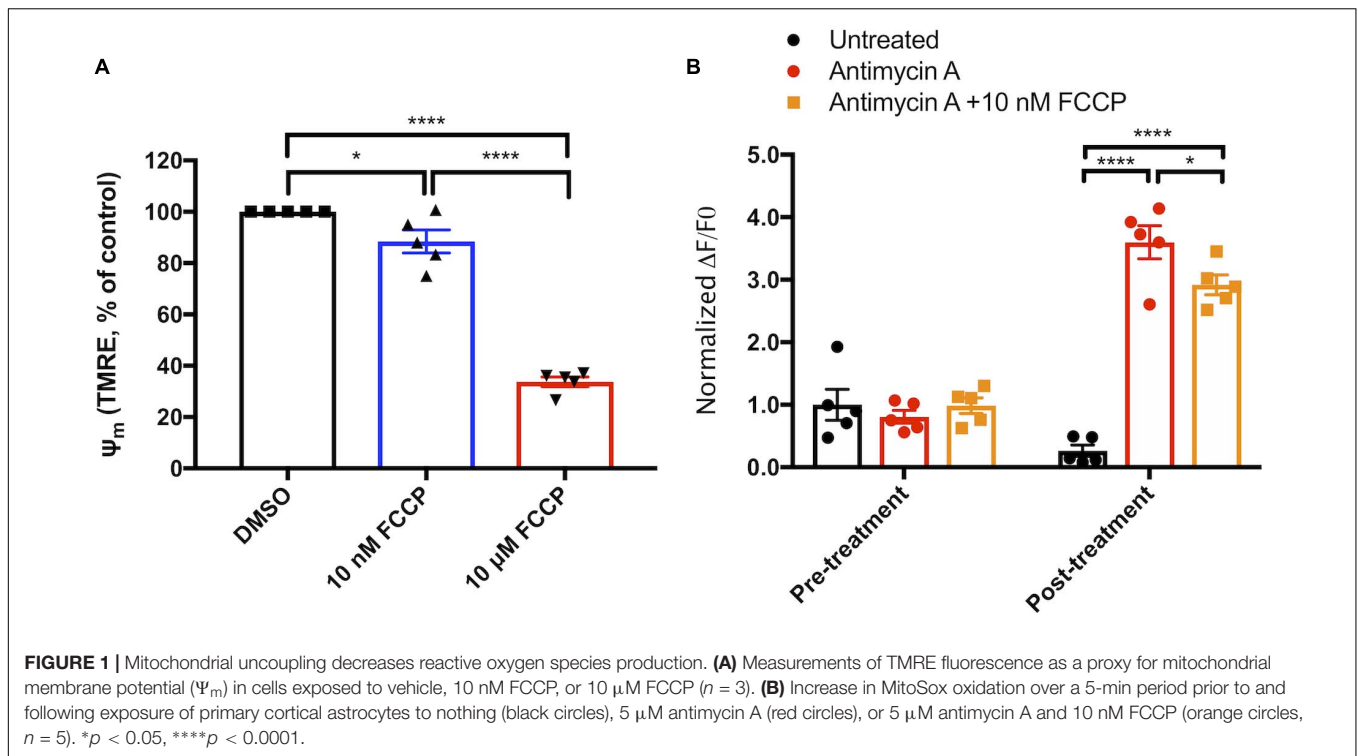

Retinal ganglion cells were counted in retinal whole-mounts using the marker RBPMS (Rodriguez et al., 2014) across three to four 317.95  $\mu\text{m} \times 317.95 \mu\text{m}$  fields, with each field centered 1000  $\mu\text{m}$  from the optic nerve head. Cell counts were converted to measurements of RGC density, averaged for a single retina, and RGC survival was calculated as a percentage of bead-injected RGC density over contralateral control PBS-injected RGC density. RGC loss or death was 100-mean RGC survival for a given sample. The counter was blinded to the identity of each sample. We did not find a significant effect of retinal quadrant on RGC density normally or with elevated IOP, and our images were therefore taken across all retinal quadrants. The mean $\pm$ SEM and median RBPMS<sup>+</sup> RGC densities in PBS-injected retinas (pooled from WT C57BL6/J and Ucp2<sup>KI</sup> controls) were 4758 $\pm$ 113 and 4738 cells/mm<sup>2</sup>, respectively. The mean $\pm$ SEM and median RBPMS<sup>+</sup> RGC densities in bead-injected retinas were 3957 $\pm$ 152 and 3858 cells/mm<sup>2</sup>, respectively, leading to an average 17% cell loss 30 days following bead injection.

## RNA Isolation and Quantitative Real-Time PCR

Flash frozen cells or tissue were lysed in TRIzol (Thermo-Fischer, Cat#:15596018) and RNA precipitated using the manufacturer's recommended procedure. Final RNA concentration was measured using a NanoDrop ND-1000 Spectrophotometer prior to reverse transcription. We reverse transcribed 300–1000  $\mu\text{g}$  RNA using SuperScript III (Thermo-Fischer, Cat#: 18080093) with random hexamers. cDNA was amplified with iQ SYBR Green Supermix (Bio-Rad, Cat#: 1708882) and amplified on a Bio-Rad iCycler. *Ucp2* primer sequences were F: 5'—GCT CAG AGC ATG CAG GCA TCG—3' and R: 5'—CGT GCA ATG GTC TTG TAG GCT TCG—3'. TATA-box binding protein (*Tbp*) primer sequences were F: 5'—ACC TTA TGC TCA GGG CTT GGC C—3 R: 5'—GTC CTG TGC CGT AAG GCA TCA TTG—3'. Cq's from *Ucp2* amplification were normalized against *Tbp* and controls using the  $\Delta\Delta\text{C}_t$  method. Expression of *Ucp2/Tbp* in DBA2J retinas was analyzed from data deposited in the NCBI Gene Expression Omnibus (Geo) by Howell et al. (2011), under the accession GSE26299.

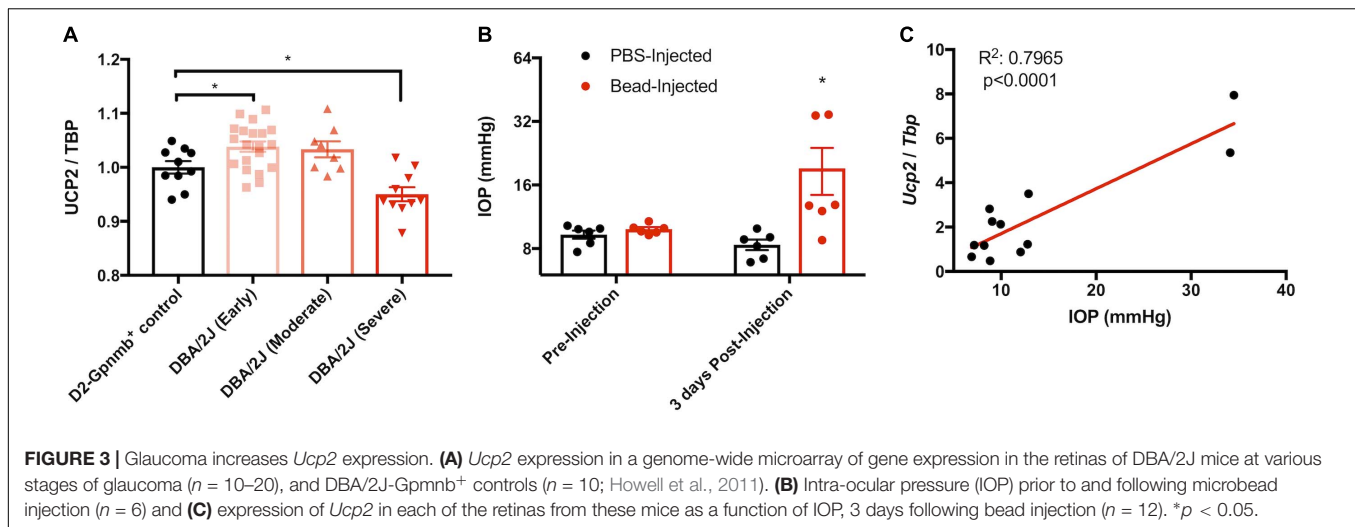

## Primary Astrocyte Culture

Primary mouse cortical astrocytes were isolated from postnatal day 1–4 mice as previously described (Sarafian et al., 2010;

Lapp et al., 2014). Briefly, mice were decapitated and brains were removed from the skull. In tissue culture medium, a  $\sim 1$  cm portion of superior cerebral cortex was pinched off of the brain using curved forceps. Meninges were removed, and the tissue was triturated with a sterile flame-polished glass Pasteur pipette until it formed a single cell suspension, approximately  $20\times$ . The suspension was filtered through a 70  $\mu$ m cell strainer (Corning, Cat#: 352350) to remove larger debris, centrifuged at  $500 \times g$  and  $4^\circ C$  for 5 min, resuspended in growth medium (Dulbecco's Modified Eagle's Medium/Ham's F12 supplemented with 2 mM L-glutamine, 15 mM HEPES, 10% fetal bovine

serum, and 10 ng/mL gentamicin), and plated in a T-25 tissue culture flask. Cells were grown at  $37^\circ C$  in a 5%  $CO_2$ /balance air atmosphere. After the cells reached confluence, between 7–14 days *in vitro* (DIV), contaminating cells were shaken off by rotating at 250 RPM overnight. Astrocyte-enriched cultures were plated at 30,000 cells/well on black tissue-culture-treated 96-well plates (Corning, Cat#3603) and used at passage #2 or 3, allowing at least 48 h following medium replacement before experimentation. All cells used in this study were exposed to 1  $\mu$ M 4-hydroxytamoxifen (Sigma, Cat#: H6278) for 24 h prior to studies of Ucp2 function.

## Measurement of Mitochondrial Membrane Potential and Oxidative Status

We determined mitochondrial membrane potential ( $\Psi_m$ ) and oxidative status of primary cortical astrocytes using the mitochondrial membrane potential-sensitive dye TMRE (50 nM, ImmunoChemistry, Cat#: 9103) or the mitochondrial superoxide probe MitoSox (5  $\mu\text{M}$ , Thermo-Fischer, Cat#: M36008), which is selectively targeted to mitochondria. Cells were incubated in either dye in prewarmed assay medium (1 $\times$  PBS supplemented with 1 mM glucose and 2 mM GlutaMax, Thermo-Fischer, Cat#: 35050-061) for 30 min at 37°C, followed by two washes and imaging. MitoSox fluorescence intensity was measured using the kinetic mode of a microplate reader (BioTek Synergy II), which took serial measurements of MitoSox fluorescence over time. The rate of increase in fluorescence ( $\Delta F$ ) over 10 min was divided by initial fluorescent intensity ( $F_0$ ) for each well. This rate of increase was normalized to the mean  $\Delta F/F_0$  of control cells. We verified the utility of TMRE as an indicator of  $\Psi_m$  by simultaneously treating cells with the membrane permeant protonophore carbonyl cyanide-4-(trifluoromethoxy) phenylhydrazone (FCCP, 10  $\mu\text{M}$ , Caymen Chemical, Cat#: 15218), which depolarizes  $\Psi_m$ . Similarly, we used the mitochondrial complex III inhibitor antimycin A (AA, 5  $\mu\text{M}$ ) to stimulate ROS production and confirm the utility of MitoSox as an indicator of ROS.

## Statistical Analysis

Quantified data are represented by that group's mean  $\pm$  SEM unless otherwise indicated. We performed all statistical analyses in GraphPad Prism. We determined the statistical effect of one independent variable (such as genetic background) on two groups using a Student's *t*-test or paired sample *t*-test in cases where samples were matched (e.g., the control was the contralateral eye of the same animal). We analyzed the effect of one variable on >2 groups (e.g., comparisons of *Ucp2*<sup>KI</sup> with or without

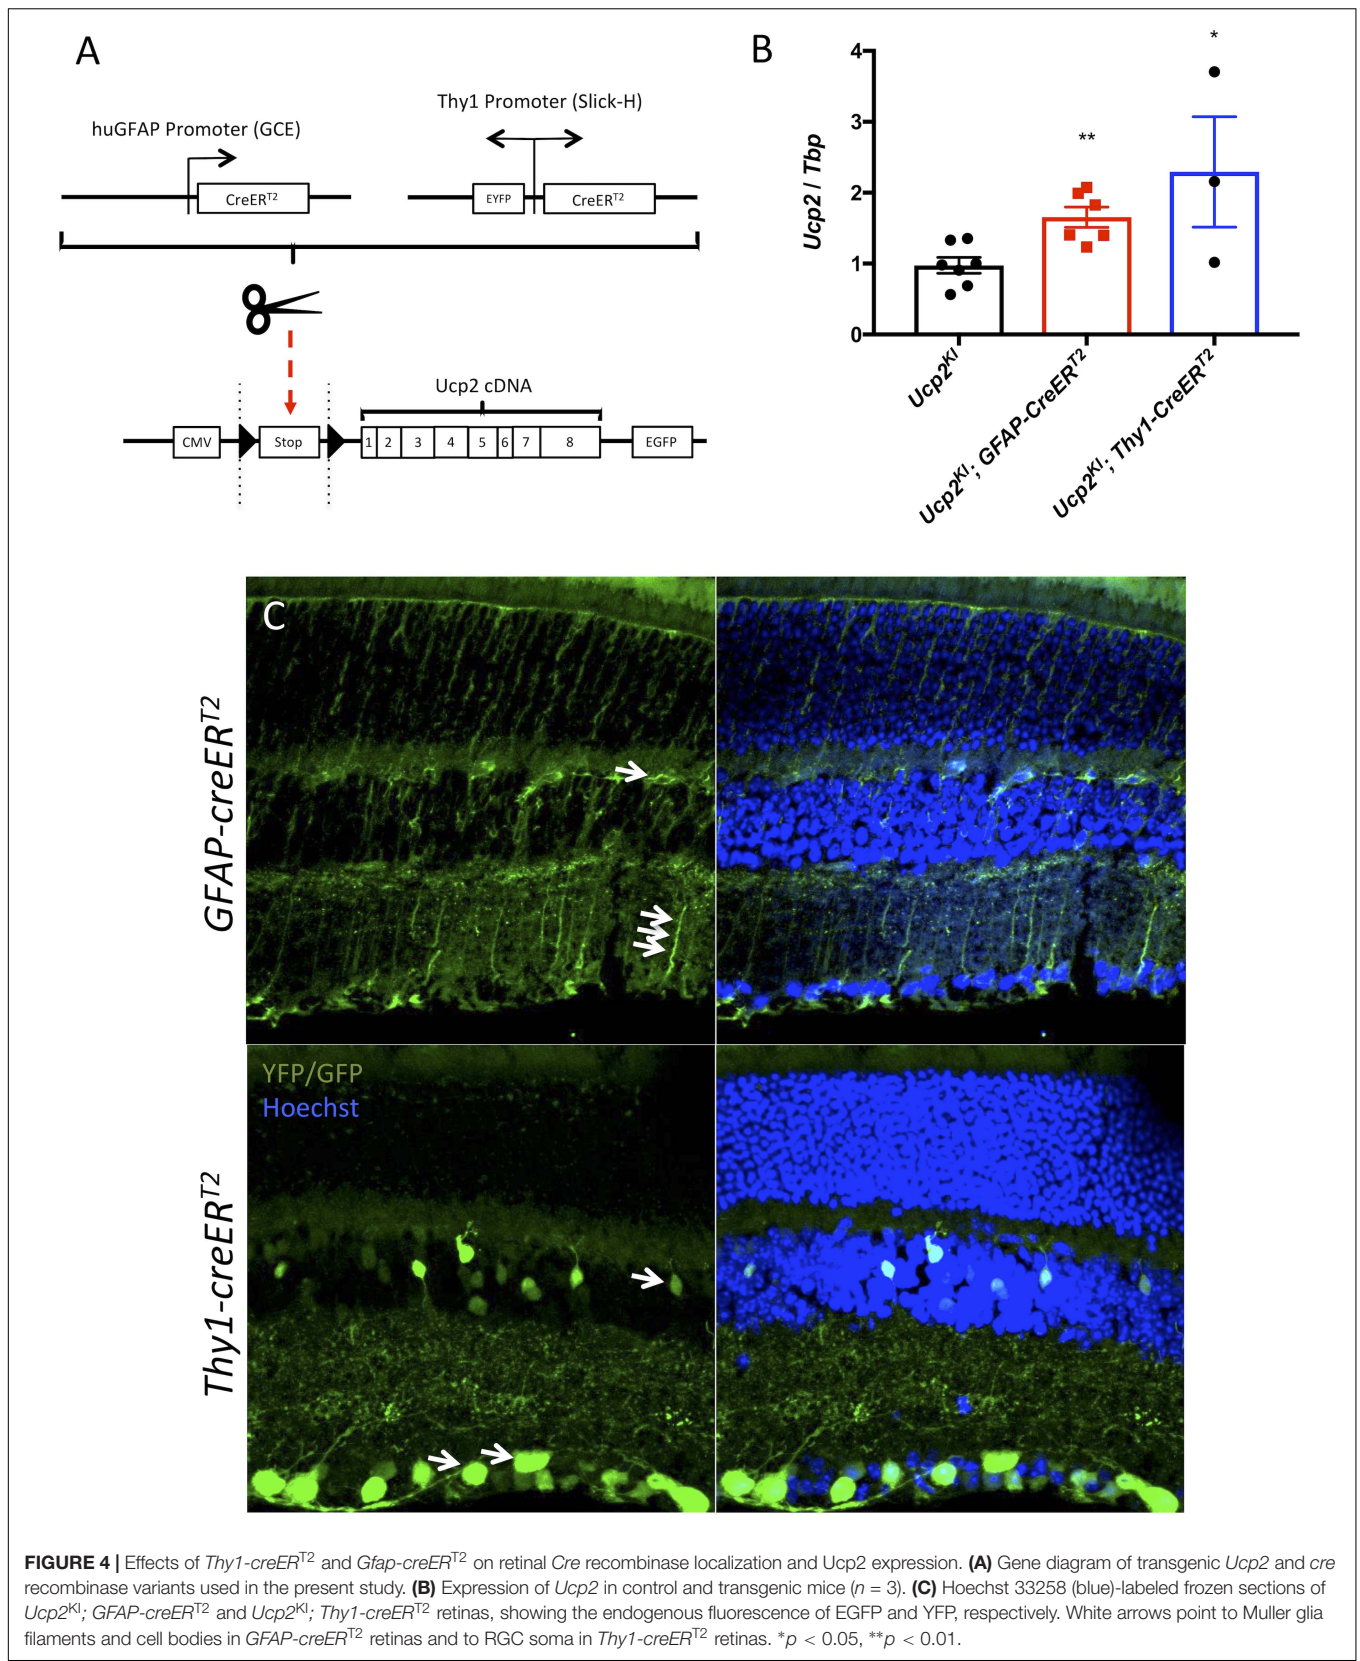

each *cre* variant) using a one-way ANOVA with a Bonferroni *post hoc* analysis. We analyzed the effect of two variables (e.g., the effects AA and FCCP on MitoSox) using a two-way ANOVA with a Bonferroni's *post hoc* analysis. The statistical significance threshold was set at  $p < 0.05$  for all tests.

In ANOVAS of unmatched samples, Prism automatically implements a Geisser-Greenhouse correction to improve statistical analysis of non-spherical data sets. In accordance with the Prism Statistics guide, we assumed sphericity in matched data sets (i.e., in bead- vs. PBS-injected eyes, and cells treated with different groups of respiratory chain inhibitors).

## RESULTS

### Exogenous Uncoupling Agents Decrease the Generation of Mitochondrial ROS

The positive association between mitochondrial membrane potential ( $\Psi_m$ ) and the production of reactive oxygen species (ROS) has been well characterized in isolated mitochondria, and we tested the hypothesis that mild mitochondrial uncoupling stimulated by an exogenous protonophore will decrease mitochondrial ROS in intact cells. We treated primary cortical astrocytes with FCCP at a low concentration to uncouple mitochondria without completely dissipating the  $\Psi_m$ , and found that 10 nM FCCP depolarized the mitochondrial membrane potential ( $\Psi_m$ ) to  $88 \pm 4\%$  of control levels, whereas  $\Psi_m$  was  $34 \pm 2\%$  of control in astrocytes treated with 10  $\mu\text{M}$  FCCP, a concentration routinely used to maximally depolarize mitochondria (10  $\mu\text{M}$ ; Figure 1A); 10 nM FCCP added to MitoSox loaded cells did not significantly alter mitochondrial superoxide generation (data not shown), so we tested the hypothesis that uncoupling will reduce ROS production by dysfunctional mitochondria. To test this hypothesis, we loaded cells with the mitochondrion-targeted superoxide probe MitoSox and treated them with the mitochondrial complex III inhibitor AA (5  $\mu\text{M}$ ). AA significantly increased the rate of MitoSox oxidation ( $p < 0.001$ ,

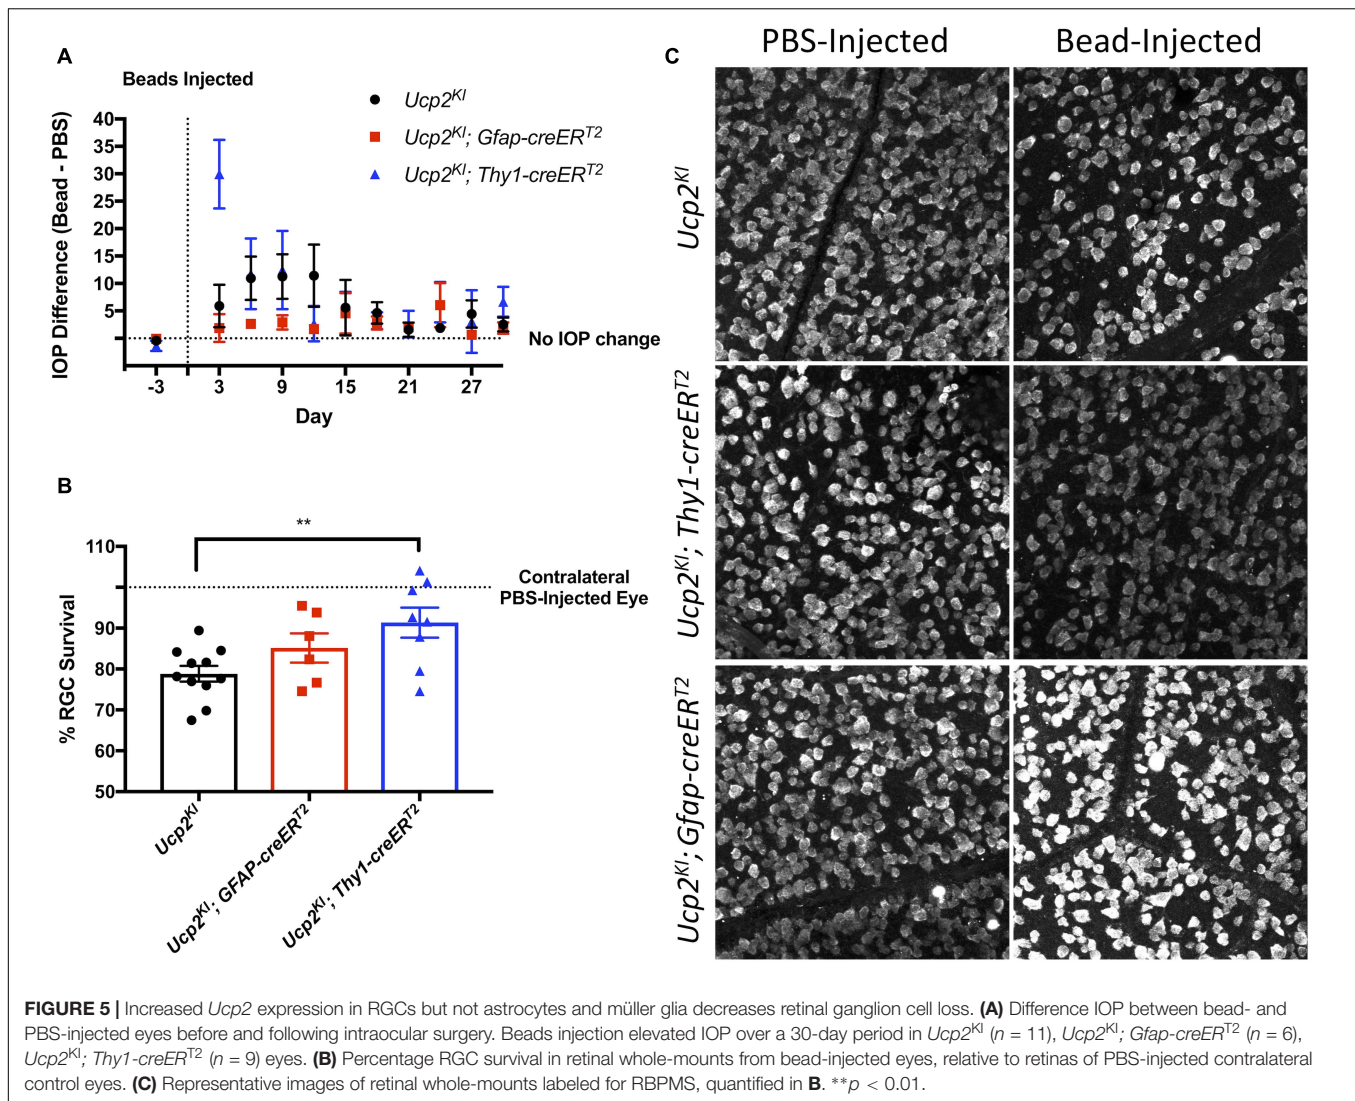

Figure 1B), but this increase was partially attenuated in cells simultaneously treated with AA and 10 nM FCCP ( $p < 0.05$ , Figure 1B). These data show that uncoupling decreases the generation of ROS by cultured astrocytes with dysfunctional mitochondria.

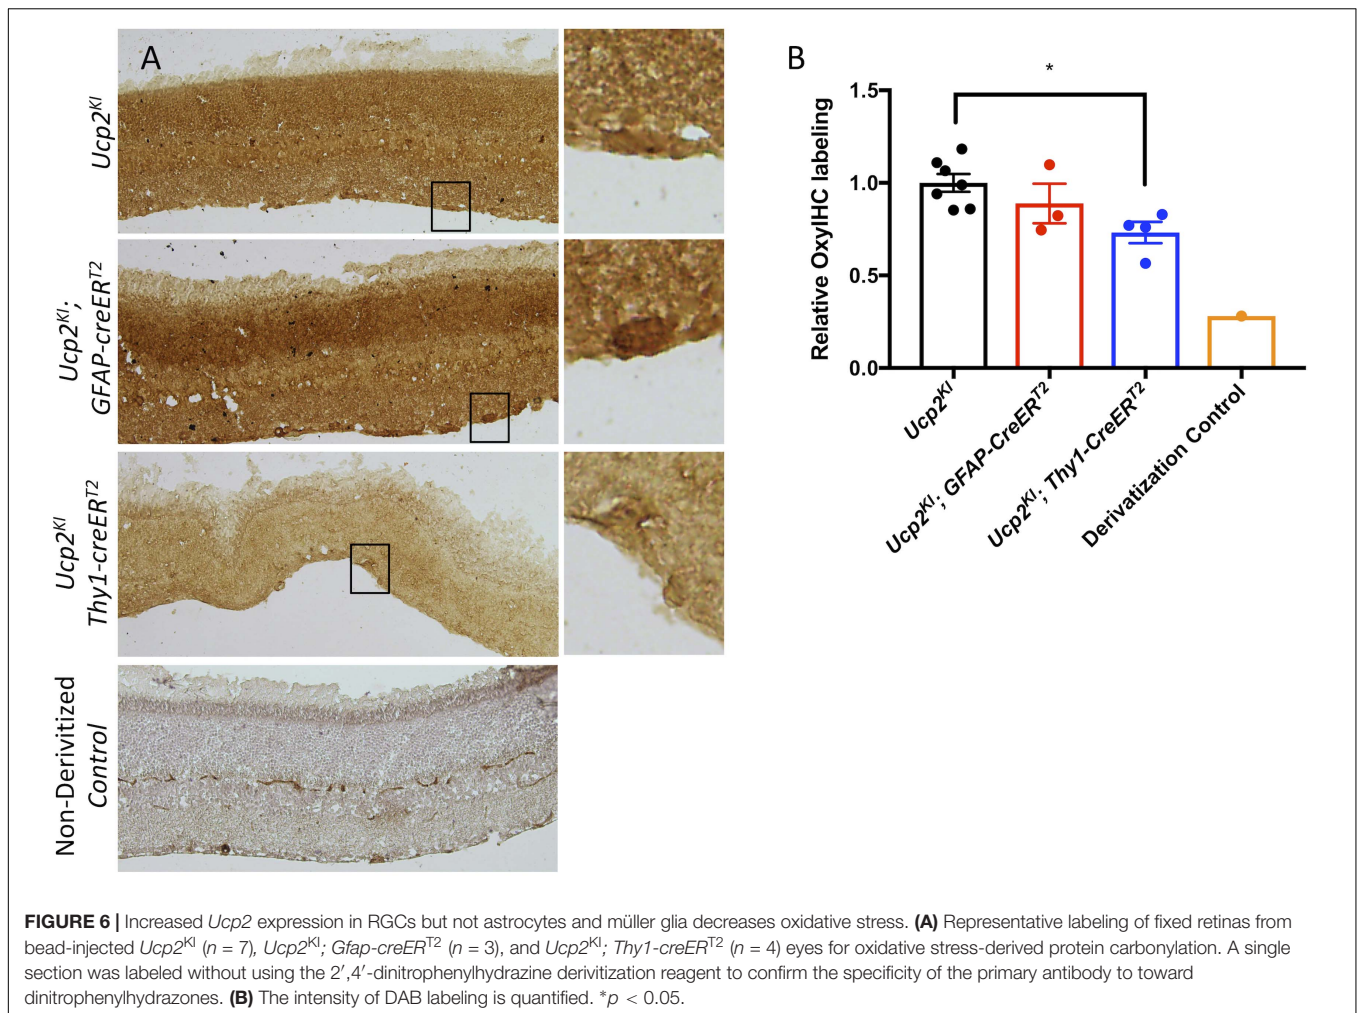

## Uncoupling Protein 2 Decreases $\Psi_m$ and ROS Production

To determine whether mitochondrial uncoupling proteins have the same cellular effects as chemical protonophores on  $\Psi_m$  and ROS production, we isolated cortical astrocytes from *Ucp2*<sup>Kl</sup>; *Gfap-creER*<sup>T2</sup> mice. *Ucp2* expression is elevated roughly threefold in *Gfap-creER*<sup>T2</sup> expressing cells of these mice following exposure to 4-hydroxytamoxifen (Figure 2A), and we tested the hypothesis that the addition of transgenic *Ucp2* will decrease  $\Psi_m$  and the generation of ROS. Our data show that *Ucp2* knock-in depolarizes  $\Psi_m$  to  $72 \pm 7\%$  of control levels ( $p = 0.0095$ , Figure 2B), with 10  $\mu\text{M}$  FCCP decreasing TMRE fluorescence to  $54 \pm 5\%$  of controls ( $p = 0.0002$ ). Increasing

*Ucp2* levels decreased the production of ROS, monitored by the change in MitoSox fluorescence over time and normalized to the mean fluorescent intensity of *Ucp2*<sup>Kl</sup> control samples ( $p = 0.043$ ; Figure 2C). Together, these data show that increased *Ucp2* expression decreases  $\Psi_m$  and mitochondrial ROS, which may be similar in mechanism to the protective effects promoted by 10 nM FCCP.

## Elevated IOP Increases *Ucp2* Expression

To determine whether *Ucp2* expression is positively or negatively related to the progression of glaucoma, we analyzed publicly available data from a microarray that determined gene expression changes in the retina and optic nerve heads of 10.5 month old DBA/2J mice and DBA/2J; *Gpnmb*<sup>+</sup> controls (Howell et al., 2014). DBA/2J are genetically predisposed toward glaucoma, and DBA/2J; *Gpnmb*<sup>+</sup> controls are genetically identical to these mice, except for in the *Gpnmb* gene, for which these control mice express a WT copy. Relative to the housekeeping gene *Tbp*, *Ucp2* expression is elevated

early in glaucoma, but decreases with increasing disease severity ( $p < 0.05$ , **Figure 3A**). We confirmed these data in a microbead model of glaucoma, and found that 3 days following microbead injection, IOP is significantly elevated ( $p < 0.05$ , **Figure 3B**). Following IOP measurement, we determined *Ucp2* expression in the retinas of these mice, and found that *Ucp2* expression increases proportionally with IOP ( $r^2=0.8$ ,  $p = 0.0001$  **Figure 3C**). These data suggest that *Ucp2* may play a role in the retinal response to IOP elevation.

### Elevated *Ucp2* Expression in RGCs but Not Astrocytes or Müller Glia Is Protective Against Glaucoma

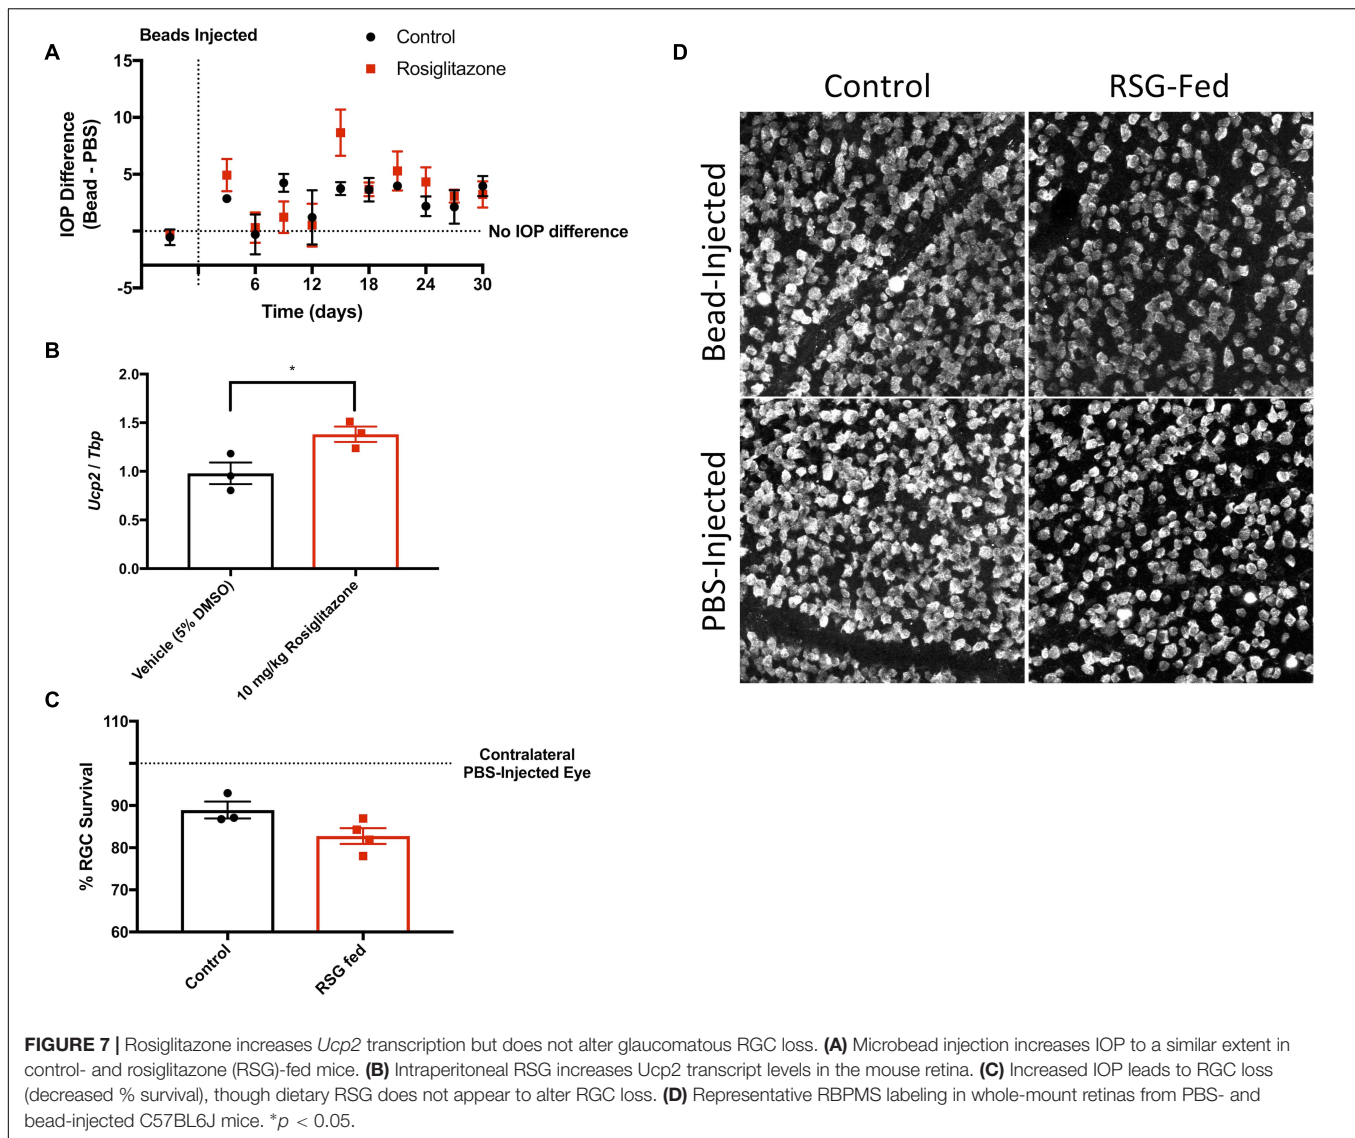

To determine whether the protective effects of *Ucp2* expression in cells translate to the same *in vivo* system, we used mice in which *Ucp2* expression can be increased in *Gfap*- or *Thy1*-expressing cells following exposure to tamoxifen (**Figure 4A**). Following eight consecutive 100 mg/kg/day injections, we found that *GFAP-creER*<sup>T2</sup> expression increased *Ucp2* transcript levels to  $165 \pm 14\%$  of control ( $p < 0.01$ ,  $n = 6$ ), and *Thy1-creER*<sup>T2</sup>

increased *Ucp2* to  $229 \pm 77\%$  of *Ucp2*<sup>KI</sup> controls ( $p < 0.05$ ,  $n = 3$ , **Figure 4B**).

Although *Thy1-creER*<sup>T2</sup> retinas express YFP both before and following exposure to tamoxifen, *GFAP-creER*<sup>T2</sup> retinas only express eGFP following LoxP excision. We show that eGFP and YFP are present in the retina, with localizations consistent with *Gfap*-expressing glia and RGCs, respectively, for the *GFAP-creER*<sup>T2</sup> and *Thy1-creER*<sup>T2</sup> transgenes (**Figure 4C**). The white arrows indicate regions of endogenous fluorophore expression, corresponding to Müller glia cell bodies and fibers (top image), as well as RGC soma (bottom image) (**Figure 4C**). Notably, *Thy1-creER*<sup>T2</sup> expression was not limited to the ganglion cell layer, implying cre activity in some inner nuclear layer cells.

We injected microbeads or PBS in to the anterior chambers of these mice, elevating IOP by an average of 5.3 mmHg in *Ucp2*<sup>KI</sup> control mice ( $n = 11$ ), 2.4 mmHg in *Ucp2*<sup>KI</sup>; *GFAP-creER*<sup>T2</sup> mice ( $n = 6$ ), and 7.5 mmHg in *Ucp2*<sup>KI</sup>; *Thy1-creER*<sup>T2</sup> mice ( $n = 9$ , **Figure 5A**). Bead injection in control mice caused a significant loss in RGCs (A  $19 \pm 3\%$  reduction in RGC density) that was attenuated in mice overexpressing *Ucp2* in RGCs (*Ucp2*<sup>KI</sup>; *Thy1-creER*<sup>T2</sup>, a  $10 \pm 4\%$  reduction), but not in *Ucp2*<sup>KI</sup>; *GFAP-creER*<sup>T2</sup> mice (a  $15 \pm 4\%$  reduction,

**Figures 5C,D).** These data demonstrate that *Ucp2* decreases RGC loss due to elevated IOP over a sub-acute timeframe, and also that the beneficial effects of *Ucp2* are cell autonomous, as *Ucp2*-overexpression in *GFAP*-positive glia is insufficient to decrease glaucoma-related RGC loss (**Figure 5C**). The protective effects of *Ucp2* expression coincided with significant decreases in oxidative protein carbonylation, measured by OxyIHC labeling. Bead-injected retinas from *Ucp2*<sup>K1</sup>; *Thy1-creER*<sup>T2</sup> mice ( $n = 4$ ) were labeled  $27 \pm 6\%$  less strongly than corresponding *Ucp2*<sup>K1</sup> controls ( $p < 0.05$ ,  $n = 7$ ). In contrast, labeling of *Ucp2*<sup>K1</sup>; *GFAP-creER*<sup>T2</sup> retinas was non-significantly reduced by  $11 \pm 11\%$  ( $n = 3$ , **Figures 6A,B**) relative to controls.

### Transcriptional Activation of *Ucp2* Is Insufficient to Decrease Microbead-Induced RGC Loss

Past literature suggests that *Ucp2* transcription is in part regulated by a PGC1- $\alpha$ /PPAR- $\gamma$  axis (Chen et al., 2006;

Donadelli et al., 2014). RSG is an FDA-approved PPAR- $\gamma$  agonist. We confirmed that retinal *Ucp2* expression can increase 24 h following exposure to 10 mg/kg RSG (**Figure 7B**), and hypothesized that due to transcriptional activation of *Ucp2*, dietary RSG confers the same resistance to damage in glaucoma as transgenic *Ucp2* overexpression. To test this hypothesis, we increased IOP in control- and RSG-fed WT mice (**Figure 7A**) and measured RGC loss 30 days following bead injection. There was an  $11 \pm 2\%$  loss in RGC density in bead-injected eyes of WT control mice ( $n = 3$ ), compared to a  $17 \pm 2\%$  loss in RSG-fed mice ( $n = 4$ ). The degree of cell loss was generally lesser than for *Ucp2*<sup>K1</sup> controls, which can be explained by the more advanced age of these mice (3.8 months), which has been demonstrated to reduce the effectiveness of RGC loss following bead injection (Cone et al., 2010). Regardless, the result of this pilot study on the effects of RSG ran contrary to our expectations and did not decrease RGC death, and in fact appeared to non-significantly increase RGC loss (**Figures 7C,D**).

## DISCUSSION

Mild levels of ROS are important signals of mitochondrial damage (Frank et al., 2012) among other physiological signals (Angelova and Abramov, 2016). When ROS production exceeds the capacity for detoxification by antioxidants, they damage cellular components in a variety of pathogenic conditions (Elfawy and Das, 2019). More reduced electron transport chain metabolites (NADH, coenzyme Q<sub>10</sub>) are better able to form ROS. Inhibitors of electrons transport, such as the Coenzyme Q<sub>10</sub>-cytochrome C Oxidoreductase (complex III) inhibitor AA, increase the accumulation of reduced electron carriers and consequently drive mitochondrial ROS production (Quinlan et al., 2011). However, ROS production is partially dependent on a high  $\Psi_m$  (Korshunov et al., 1997; Miwa et al., 2003), which can be depolarized by either an FCCP- or Ucp2-mediated increase in proton conductance (Nègre-Salvayre et al., 1997). These data were mainly gathered in isolated mitochondria. Tissue mitochondrial quantity is too small in the retina and optic nerve, and with our currently available tools, we cannot determine endogenous RGC and optic nerve head astrocyte-specific relations between ROS and  $\Psi_m$ , if such relations exist. However, given identical bioenergetic circumstances most cellular mitochondria should react similarly to agents that alter mitochondrial coupling or electron transport. Similarly, our use of transgenic *Ucp2* overexpression is not under the control of endogenous regulatory factors, which are more likely to differ with cell type and condition.

Given the similarity of mitochondrial respiratory chain function across cell types, we used primary cortical astrocytes to demonstrate the concepts that AA-stimulated increases in ROS production that are attenuated by decreases in  $\Psi_m$  (Figure 1), and that *Ucp2* decreases ROS production (Figure 2). While these data lend support to the association between mitochondrial  $\Psi_m$  and ROS as well as the control of ROS by *Ucp2*, the most important evidence for their effect on cell and tissue physiology normally and during glaucoma must be determined *in vivo*.

Mitochondria are damaged in both glaucomatous retinal and optic nerve tissue (Coughlin et al., 2015) as well as in systemic circulation of glaucoma patients (Van Bergen et al., 2015). Mitochondria are a major source of ROS, so mitochondrial dysfunction in glaucoma is a likely source of ROS in the same tissues (Feilchenfeld et al., 2008; Chidlow et al., 2017). As with cultured cells, partial dissipation of tissue mitochondrial  $\Psi_m$  may decrease the generation of ROS in glaucoma (Figure 6).

*Ucp2* expression is in fact altered during different stages of glaucoma, and appears to increase with increasing IOP (Figure 3). In pilot samples, however, we note that longer periods (30 days) following bead injection result in a depression of *Ucp2* expression to roughly 80% of contralateral controls (data not shown). This is consistent with other studies of *Ucp2* expression following a damaging insult, wherein tissue *Ucp2* expression peaks 3–5 days after an insult (Rupprecht et al., 2012; Dutra et al., 2018). It is likely that over time in glaucoma, *Ucp2* levels may fall, and this may be correlated

with RGC loss (Howell et al., 2011). If increased ganglion cell *Ucp2* expression reflects a physiological response to increased ROS early in glaucoma, artificially increasing *Ucp2* may increase the ability of that stress response to increase cell survival. We indeed found an increase in retinal *Ucp2* expression following microbead injection (Figure 5). The hypothesis that *Ucp2* improves cell survival following a cellular stressor is also strongly supported by previous studies (Diano et al., 2003; Mattiasson et al., 2003; Andrews et al., 2005; Barnstable et al., 2016), but the novelty of our study is that in rodent models of glaucoma, RGC death is progressive over time (Huang et al., 2018), suggesting that *Ucp2* is not exclusively protective during acutely stressful conditions, but also during sub-acute neurodegeneration, decreasing the accumulation of oxidative damage (Figure 6) and bead-induced RGC loss.

*Ucp2*-mediated neuroprotection is dependent on cell type, as we show that greater *Ucp2* levels in *Gfap*-expressing glia do not significantly alter RGC loss or oxidative stress-derived protein carbonyls compared to controls (Figures 5, 6). A larger sample size may benefit these studies and be sufficient to demonstrate a glial-derived neuroprotective effect, supported by a trend toward decreased oxidative stress and RGC loss in *Ucp2*<sup>KI</sup>; *GFAP-creER*<sup>T2</sup> mice, but overall the data argue for much weaker if any *Ucp2*-mediated neuroprotection from glial cells than from RGCs. This seems to suggest that changes in mitochondrial dynamics within *Gfap*-expressing glia of the retina may not be central for the progression of glaucoma, which is unexpected given the many changes they undergo over the course of the disease (Woldemussie et al., 2004) and the protection they give to RGCs (Kawasaki et al., 2000).

Rosiglitazone is a PPAR- $\gamma$ -dependent transcriptional activator of *Ucp2* (Medvedev et al., 2001; Chen et al., 2006), and increases retinal *Ucp2* expression (Figure 7), but does not seem to promote *Ucp2* mediated neuroprotection in the microbead model of glaucoma. PPAR- $\gamma$  appears to be expressed with high specificity in müller glia cells of the rodent retina (Zhu et al., 2013), and while the failure of RSG to protect RGCs was initially surprising, it likely increases the transcription of glial *Ucp2*. *Ucp2* overexpression in *Gfap*-expressing glia failed to protect RGCs, so our experiments using RSG-fed and *Ucp2*<sup>KI</sup>; *GFAP-creER*<sup>T2</sup> mice largely support each other. PPAR- $\gamma$  agonism with pioglitazone is sufficient to decrease RGC loss following optic nerve crush in rats (Zhu et al., 2013) or retinal ischemia/reperfusion injury in mice (Zhang et al., 2017), suggesting that glial *Ucp2* expression may be protective against more acute retinal insults. This protection may also result from the increase in neural PPAR- $\gamma$  following optic nerve crush (Zhu et al., 2013), which would allow for agonist-stimulated *Ucp2* mRNA expression that is likely subject to multiple endogenous regulatory mechanisms (Donadelli et al., 2014), unlike the *Ucp2* derived from our transgenic mice (Toda et al., 2016). Alternatively, PPAR- $\gamma$  could theoretically promote multiple counteracting effects that render transcriptional stimulation of *Ucp2* unimportant in glaucoma. For example, activation of PPAR- $\gamma$  promotes fatty acid oxidation (Benton et al., 2008), increasing use of a bioenergetic substrate that may directly

increase ROS generation (St-Pierre et al., 2002) and thus mask a Ucp2-dependent anti-oxidative effect. Regardless, a larger study of Ucp2 and PPAR- $\gamma$  in retinal disease that uses multiple models and agonists/antagonists may yield a clearer picture that captures the cell type specific dynamics of these factors, and changes during different paradigms of retinal damage.

Overall, our data suggest that the greatest protection against RGC loss can be provided by stimulating Ucp2 expression in RGCs. Expression of this gene in other cell types may not be harmful, but our results suggest that the choice of therapeutic target should be dictated in part by cell type. The expression and activity of this protein is also tightly regulated, so the future studies on Ucp2-mediated neuroprotection should also focus on the factors that manipulate Ucp2 transcription, translation, and functional activity.

## DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.
