Background: The beneficial effects of exercise training on depressive symptoms are well-established. In the past years, more research attention has been drawn to the specific effects of exercise training on depressive symptoms in somatically ill patients. This reviews aims at providing a comprehensive overview of the current findings and evidence of exercise interventions in somatic disorders to improve depressive symptoms.

Methods: We systematically searched PubMed and Cochrane databases and extracted meta-analyses from somatically ill patients that underwent exercise interventions and provided information about the outcome of depressive symptoms.

Results: Of the 4123 detected publications, 39 were selected for final analysis. Various diseases were included (breast-cancer, prostate cancer, mixed-cancer, cardiovascular disease, coronary heart disease, hemodialysis, fibromyalgia syndrome, acute leukemia, other hematological malignancies, heart failure, HIV, multiple sclerosis, mixed neurological disorders, Parkinson's disease, stroke, ankylosing spondylitis, traumatic brain injury, lupus erythematoses). Most meta-analyses (33/39) found beneficial effects on depressive symptoms, but quality of the included studies as well as duration, intensity, frequency, and type of exercise varied widely.

Conclusion: Exercise training has the potential to improve depressive symptoms in patients with somatic disorders. For specific training recommendations, more high quality studies with structured exercise programs and better comparability are needed.

Keywords: depressive symptoms, training, aerobic, somatic disease, comorbidity

INTRODUCTION

Depression alone and comorbid with other chronic somatic diseases accounts for significant disease burden worldwide (1, 2). By 2030, depression is in addition to HIV/AIDS and ischemic heart disease assumed to be one of the three leading causes of burden of disease (3). Exercise therapy in depressive patients, as an independent intervention and as an adjunct intervention to antidepressant medication or psychotherapy, has been discussed to improve clinical outcomes in somatic diseases (4, 5). Compared to pharmacological treatment, the beneficial effects of exercise seem to be similar and are present at short-term and during follow-up periods of up to one year (6, 7). Especially for somatically unstable patient, this offers new treatment perspectives without the common side-effects of psychopharmacological medication. Usually both the depressive symptoms and the underlying somatic condition improve as a consequence of exercise therapy.

In a large World Health Survey of 245 404 participants from 60 countries, an average between 9.3 and 23.0% of participants with one or more chronic physical diseases had comorbid depressive symptoms (2). For numerous somatic diseases, an association with depression is well-established. For example, patients with multiple sclerosis (8), stroke (9), parkinson's disease (10), diabetes mellitus (11), breast cancer (12) or heart failure (13) have an elevated risk for developing a major depressive disorder (MDD). From a psychiatric perspective, it is important to note that a recently published study with 1,237,194 participants showed that individuals who exercised (various types of disciplines) had 1.49 (43.2%) fewer days of poor mental health in the past month than non-exercising individuals (14).

As the comorbid physical diseases often complicate the pharmacological treatment of depressive symptoms, further research approaches with a focus on alternative therapy options are urgently needed. Based on the beneficial effects of physical exercise in MDD (15), prior studies investigated the effects of exercise in patients with somatic disorders and comorbid depressive symptoms. A meta-analysis of different chronic illnesses including stroke, ischemic heart attack, fibromyalgia, dementia, and other psychiatric diseases, revealed a significant overall reduction of depressive symptoms. The majority of effects were derived from cardiovascular diseases, chronic pain and fibromyalgia (16). The results lead to the conclusion that physical exercise seems to have positive effects on depressive symptoms in patients with various somatic diseases without subdividing the different diseases with specific recommendations. However, a comprehensive overview of the available evidence of how exercise may improve depressive symptoms in patients with somatic diseases is lacking.

In this systematic meta-review, we will provide a detailed overview of recent meta-analyses evaluating different somatic diseases with comorbid depressive symptoms. The efficacy and the types and durations of exercise will be analyzed. Up to date, meta-analyses of specific diseases or disease groups (e.g., cardiovascular diseases) have been published as well as meta-analyses comprising different somatic diseases with an emphasis on cardiovascular diseases, fibromyalgia and pain (16). With our review, we aim to close this gap and point to limitations of prior studies as well as possible future research strategies.

METHODS

We systematically searched PubMed and Cochrane databases with all combinations of the following search terms: depressive disorder OR depression AND exercise, depressive disorder OR depression AND physical activity, depressive disorder OR depression AND endurance training, depressive disorder OR depression AND training, depressive disorder OR depression AND resistance training, depressive disorder OR depression AND aerobic, depression OR depressive disorder AND somatic AND exercise, depression OR depressive disorder AND physical illness. The database search was last updated on 31th July 2018. All citations were screened for relevance by title in a first step, by abstract in a second step and by

full-text in a last step. In all included meta-analyses, the citations were screened manually for further relevant meta-analyses that may have not been detected by the systematic search. The systematic literature search and selection was performed by AR, the selection was afterwards reviewed independently by SK.

Both AR and SK retrieved the relevant information and the results were compared. In case of disagreement, a third author (AH) was consulted. Inclusion criteria were: meta-analysis investigating the effects of exercise on depressive symptoms in patients with comorbid physical illness based on interventional trials, published within the past 10 years. Exclusion criteria contained meta-analyses published earlier than within the past 10 years, systematic reviews without meta-analyses, meta-analyses in non-English language, meta-analyses only investigating depressive patients with no somatic comorbidities, lack of data post-intervention. No limitations were defined for the type or duration of exercise and the type of somatic illness.

RESULTS

Study Selection

The initial search without further restrictions resulted in 103,468 citations. After limiting the citations for the past 10 years, 60,430 citations remained. When only considering the meta-analyses, 4,123 citations remained and after eliminating duplicates, 981 citations were included for further analysis. The screening on title-level eliminated 869 citations (112 remaining), the screening on abstract-level another 63 citations (49 remaining). After full-text screening, 39 citations remained for final analysis (see **Figure 1**).

Study Characteristics

Table 1 provides an overview of the included somatic diseases. The duration of the single studies varied between three (46) to 52 (21) weeks, the intensity between one time (51) and seven times (37) per week and the duration of the sessions between 30 and 122 min (16). Adherence rate was solely reported in two meta-analyses (21, 22) and intensity of the training with heart rate controlled exertion in one meta-analysis (37). The interventions consisted of aerobic exercise, resistance training, balance training, yoga, moderate cycling, walking, nordic walking, running, swimming, tai chi chuan, qigong, Bobath exercises, jogging, calisthenics. Across all trials, the mean sample size was 658 with a minimum of 39 (28) and a maximum of 3,425 (36). Depressive symptoms were rated with different questionnaires (observer or self-assessment): BDI (Beck Depression Inventory), CDI (Children Depression Inventory), CES-D (Center for Epidemiological Studies Depression Scale), DASS (Depression Anxiety Stress Scales), GDS (Geriatric Depression Scale), HAD (Hospital Anxiety and Depression Scale), HAM-D (Hamilton Rating Scale for Depression), SCL-90 (Symptom Checklist-90), TAS (Toronto Attitude Scale), POMS (Profile of Mood States), SAS (Symptom Assessment Scale), CSDD (Cornell Scale for Depression in Dementia), IDS-SR (Inventory of Depressive Symptomatology Self Report), LPD (Levine-Pilowsky Depression Questionnaire), MADRS

HIV, human immunodeficiency virus.

(Montgomery-Asberg Depression Rating Scale), MDI (Major Depression Inventory), POMS (Profile of Mood States), QOL (Quality of Life), DASS (Depression Anxiety Stress Scales), TAS (Toronto Attitude Scale), MAACL (Multiple Affect Adjective Checklist), HDCDS (Hare-Davis Cardiac Depression Scale),

SDS (Self-rating Depression Scale), BSI-18 (Brief Symptom Inventory). Thus, in the different meta-analyses, various different questionnaires were used, most often self-rating questionnaires: the BDI I/II in 26, the HADS in 18 and the CES-D in 17 meta-analyses. The majority of meta-analyses included more than three different questionnaires. As observer-rating scales, HAMD was used in four and MADRS in three meta-analyses.

Risk of Bias Within and Across Studies

Most meta-analyses (51) reported about different cancer-type patients followed by neurological disorders (7). For other diseases, such as HIV, only one meta-analysis could be identified. The variety of exercise modalities and the different durations of interventions lead to a reduced general transferability of the conclusions. Recommendations regarding effects of specific interventions on depressive symptoms in specific somatic conditions can hardly be drawn. None of the trials included in the respective meta-analyses could be declared double-blind as this is challenging to fulfill with exercise interventions. The application of various different rating-scales is another potential risk of bias. Moreover, most of the included studies in the respective meta-analyses did not define depressive symptoms as primary outcome parameter.

Results of Individual Studies

A detailed summary of the included studies with inclusion/exclusion criteria, study population, intervention summary and outcomes is provided in **Tables 2, 3**.

Exercise Interventions in Cancer Patients

Exercise interventions in breast cancer patients

Our search resulted in seven meta-analyses that met the inclusion criteria. The majority found positive effects of

Aerobic interventions included but were not limited to walking, jogging, cycling, rowing, stair stepping, and swimming. Interventions may or may not have been supervised.</p> <p>Exercise-based interventions comprised one or more of the following components: range of motion (stretching), resistance training, or aerobic exercise. 3–6 weeks of duration and 2–3 sessions/week.</p>	POMS	2/10 studies evaluated depression via POMS and were included in the meta-analysis.
O'Dwyer et al. (44)	3 RCTs, N = 75	<ol style="list-style-type: none"> 1) Quasi-randomized and randomized controlled trials in SLE (systemic lupus erythematoses) comparing at least one exercise group to controls 2) Studies evaluating adults diagnosed with SLE by established criteria 3) studies with participants under 18 years of age were excluded 4) studies comparing exercise to no intervention controls, studies comparing different exercise or physical activity protocols (e.g., aerobic exercise vs. strengthening exercise), and studies comparing an exercise-based intervention to another treatment approach (e.g., relaxation) 		BDI	Overall risk of bias of these studies was unclear.
Patsou et al. (21)	14 RCTs, N = 1,701	<ol style="list-style-type: none"> 1) Written in English 2) Published in 2011 and beyond 3) Participants were adult women diagnosed with breast cancer based on mammography and biopsy 4) Included an intervention program involving physical activity 5) Randomized controlled trial (experimental) design <p>The median age of the included breast cancer survivors was 52 years. In all studies, women had been diagnosed with 0–IIc stage breast cancer.</p>	<p>Aerobic, resistance, aerobic and resistance, yoga exercises</p> <p>The length of the interventions ranged from 6 to 52 weeks.</p> <p>The reported exercise frequency was 2–3 sessions per week for the majority of the studies, while duration varied from 30 to 90 min per session and weekly exercise duration ranged from 90 to 270 min.</p> <p>All studies had over 80% up to as high as 99% retention rates, while adherence rates, when reported, varied from 70 to 92.7%.</p>	HADS, CES-D, BDI-II, POMS	The mean PEDro score of the studies was 6.1 ± 2, indicating High quality. Depression was the sole primary outcome measure in only one study, while in three more studies, depression was included either as primary or not as psychosocial/psychological outcome.
Perry et al. (54)	2 RCTs/7 non-RCTs, N = 188	<ol style="list-style-type: none"> 1) Participants aged 18 or older and have sustained a TBI (traumatic brain injury) 2) Interventions must utilize physical exercise 3) Depression-related outcome measure 	<p>Eight out of the nine studies had an aerobic intervention including treadmill, exercise bike and swimming, one study used a walking intervention. The intervention length was between 8 and 12 weeks, apart from one study which had just two sessions, 1 week apart</p> <p>Home and hospital exercise training interventions.</p>	BDI, HAM-D, POMS, BRUMS, CES-D, HADS	Majority of included trials was non-randomized, no PEDro scores provided.
Samartzis et al. (36)	9 RCTs (+ 4 RCTs with SSRI comparison), N = 3,425	<ol style="list-style-type: none"> 1) An experimental CHF patient group, and a CHF patient group as controls that received standard care 2) Patients were randomly allocated 3) Both groups were evaluated for depression before and after the intervention, by using psychometric instruments 4) data were published 		HAM-D, BDI-II, BDI, MADRS, GDS, MAACL	No PEDro scores provided. A trend for superiority of hospital-based exercise training for depression was noted.
Singh et al. (22)	14 RCTs, N = 1005	<ol style="list-style-type: none"> 1) RCTs in which at least 50% of the sample was diagnosed with Stage II+ breast cancer 2) Exercise trials 3) Trials were eligible regardless of the level of supervision provided, mode of intervention delivery, intervention duration or intensity <p>Median recruitment rate was 56% (1–96%), 15 withdrawal rate was 10% (0–41%) and adherence rate was 82% (44–99%).</p>	<p>Aerobic exercise, resistance exercise, combined,</p>	POMS, HADS, CES-D, Greene Climacteric Scale, BDI, Functional Living Index of Cancer	14/61 trials evaluated depression. 38/61 trials were rated as "high quality" according to the PEDro score.

TABLE 3 | Outcomes of the included meta-analyses.

References	Results/Main Outcomes
Adamson et al. (50)	Results from the meta-analysis yielded a small but statistically significant effect of 0.28 for depression reduction overall (SE = 0.07; 95% CI: 0.15 to 0.41; $p = 0.00$). The effect of exercise on depression is slightly larger (0.36) in the MS studies compared with the other studies (0.20), but this difference was not statistically significant.
Bergenthal et al. (46)	The pooled result of three trials ($N = 249$) for depression shows a statistically significant benefit for the exercise arm (SMD = 0.25; 95% CI: -0.00 to 0.50; $p = 0.05$).
Brown et al. (24)	Exercise provided a small overall reduction in depressive symptoms compared to standard care among all types of cancer $d_s = -0.13$, 95% CI: -0.26 to -0.01). Collectively, the 40 effect sizes lacked homogeneity $I^2 = 55%$, 95% CI: 35 to 68, $p < 0.001$. Subgroup analysis by cancer type revealed significant reductions in depressive symptoms among breast cancer survivors $d = -0.17$, 95% CI: -0.32 to -0.02, but no significant difference in depressive symptoms among prostate, leukemia, lymphoma, and colorectal cancer survivors.
Buffart et al. (25)	After excluding outliers, yoga resulted in significant large reductions in depression ($d = -0.69$; 95% CI: 1.02 to -0.37).
Carayol et al. (17)	Exercise resulted in an improvement of depressive symptoms ($d = -0.275$, 95% CI: -0.457 to -0.094, $p = 0.003$). $I^2 = 39%$ ($p = 0.09$).
Chung et al. (38)	Exercise improved depressive symptoms ($d = -1.233$, SE = 0.482, 95% CI: -2.177 to -0.289, $p = 0.010$). Heterogeneity: $\chi^2 = 23.80$, $p < 0.001$; $I^2 = 87.40%$
Craft et al. (26)	Mean ES of (-0.22, 95% CI: -0.43 to -0.009; $p = 0.04$) under a random effects model, when comparing exercise interventions to control groups.
Cramer et al. (19)	Evidence for large short-term effects were found for depression (SMD = -1.59, 95% CI: -2.68 to -0.51; $p < 0.01$). Heterogeneity: $\text{Chi}^2 = 84.03$, $df = 5$ ($p < 0.00001$); $I^2 = 94%$ Long-term effects (2 studies, $N = 43$) of up to 24 weeks did not show significant results.
Cramer et al. (18)	Comparison of yoga vs. no therapy: Yoga did not appear to reduce depression (pooled SMD = -0.13, 95% CI -0.31 to 0.05; seven studies, 496 participants; low-quality evidence). Comparison of yoga vs. psychosocial/educational interventions provided moderate-quality evidence indicating that yoga can reduce depression (pooled SMD = -2.29, 95% CI: -3.97 to -0.61; 4 studies, 226 participants).
Dalgas et al. (48)	In summary the meta-analysis indicated a small beneficial effect of exercise on depressive symptoms in people with MS. The SMD across studies was ($g = -0.37$, 95% CI: -0.56 to -0.17).
Eng and Reime (52)	Overall, physical exercise resulted in less depressive symptoms over 13 studies involving 1022 patients (SMD = -0.13, 95% CI: -0.26 to -0.01, $I^2 = 6%$, $p = 0.03$) with low heterogeneity. Ten studies evaluated the effect on depressive symptoms after a period of time had elapsed following the exercise sessions (range from 10 weeks to 9 months). Physical exercise did not change depressive symptoms over these 10 follow-up studies involving 889 patients (SMD = -0.04, 95% CI: -0.17 to 0.09, $I^2 = 1%$, $p = 0.53$).
Ensari et al. (49)	The weighted mean ES was small, but statistically significant ($g = 0.36$, SE = 0.09, 95% CI: 0.18 to 0.54, $Z = 3.92$, $p < 0.001$), indicating the exercise training resulted in an improvement in depressive symptoms compared to control.
Fong et al. (27)	Measured by the Beck depression inventory, physical activity was associated with reduced depression (-4.1, 95% CI: -6.5 to -1.8; $p < 0.01$) in survivors of mixed types of cancer. Four other studies in the sample used the HADS (two) or POMS (two). The results for HADS were (-0.5, 95%CI: -2.8 to 1.7, $p = 0.64$ and for POMS -7.5, 95 CI: -16.0 to 1.0, $p = 0.09$).
Furmaniak et al. (20)	Exercise may lead to little or no improvement in depression (SMD = -0.15, 95% CI: -0.30 to 0.01, test for overall effect: $Z = 1.86$; $p = 0.062$). Heterogeneity: $\text{Tau}^2 = 0.0$; $\text{Chi}^2 = 3.73$, $df = 5$; $p = 0.59$; $I^2 = 0.0%$.
Gomes Neto et al. (39)	Exercise lead to a reduction in depression symptoms (-7.32; 95% CI: -9.31 to -5.33). Test for overall effect size $Z = 7.21$, $p < 0.00001$.
Graven et al. (53)	When the data from the two studies was pooled; (SMD = -2.03, 95% CI: -3.22 to -0.85) immediately after the intervention phase (note, different time points were used in the two studies for the follow-up assessment).
Herring et al. (16)	Exercise training significantly reduced depressive symptoms by a heterogeneous mean effect of 0.55 (95% CI: 0.31 to 0.78, $p < 0.001$). A significant improvement in fatigue ($\beta = 0.37$, $Z = 2.21$, $p \leq 0.03$) accounted for significant variation in the overall effect of exercise on depressive symptoms.
Langhorst et al. (41)	Meditative movement therapies improved depressive symptoms (SMD = -0.49, 95% CI: -0.76 to -0.22, $p = 0.0004$ Heterogeneity $I^2 = 27%$; $\text{Tau}^2 = 0.03$). 2 studies evaluated the follow-up ($N = 132$), with no significant improvement of depressive symptoms. In subgroup analyses, only Yoga yielded significant effects on depression at final treatment.
Liang et al. (43)	A statistically significant difference was observed (MD = -2.31, 95% CI: -3.33 to -1.30, $p = 0.001$), which indicated that home-based exercise interventions reduced the depression scores, compared to the control groups. No significant heterogeneity between home-based exercise groups and control groups ($p = 0.24$, $I^2 = 30%$).
Lin et al. (29)	Improvement of depressive symptoms (-0.95, 95% CI: -1.55 to -0.36, test for overall effect: $Z = 3.15$, $p = 0.002$). Heterogeneity: $\tau^2 = 0.63$, $\chi^2 = 66.81$, $df = 7$, $p < 0.00001$; $I^2 = 90%$.
Lin et al. (28)	No significant effects were found for depression and health-related quality of life. (No SMD or CI provided)

(Continued)

TABLE 3 | Continued

References	Results/Main Outcomes
Liu et al. (35)	The Thai Chi group had a significantly lower level of depression (SMD 9.42, 95% CI: 13.59 to 5.26, $p < 0.001$, $I^2 = 81%$, $N = 168$) compared with the non-active control groups.
Newby et al. (31)	Exercise interventions significantly reduced depressive symptoms (Point estimate -0.961 , SE = 0.319, CI 95% -1.585 to -0.337 , $Z = -3.017$, $p = 0.003$).
O'Brien et al. (47)	One meta-analysis was performed and demonstrated a significant improvement in the depression-dejection subscale of the Profile of Mood States Scale (POMS) by a reduction of 7.68 points for participants in the aerobic exercise intervention group compared with the non-exercising control group (95% CI: -13.47 to -1.90 , $p = 0.009$, $I^2 = 94%$, $p < 0.0001$).
O'Dwyer et al. (44)	A meta-analysis including three studies found significantly lower depression scores in the exercise groups compared to controls (SMD = -0.40 SD; 95% CI: -0.71 to -0.09 , test for overall effect size $Z = 2.54$, $p = 0.01$).
Patsou et al. (21)	Reduction in depressive symptoms showed a small to moderate effect of depressive symptoms in favor of the exercise $g = -0.38$ (95% CI -0.89 to 0.13 , $p = 0.14$). With regard to the type of the exercise intervention, aerobic interventions yielded a large and significant effect on depression at the last follow-up (3–6 months) measurement compared with the control groups ($g = -1.23$, 95% CI: -1.97 to -0.49 , $p = 0.001$).
Perry et al. (54)	This represents a statistically significant, positive small to medium overall effect size of physical exercise to reduce depressive symptoms in people following TBI (SMC = 0.48, 95% CI = 0.16 to 0.81). Tests of heterogeneity were significant ($p < 0.01$), confirming that heterogeneity was present amongst the studies included in the analysis.
Samartzis et al. (36)	Interventions using exercise training appeared more effective compared to usual care (SMD = 0.391, 95% CI: 0.213 to 0.569). There was a trend for SSRI superiority compared to exercise training for improving depression ($Q = 3.257$, $df = 1$, $p = 0.071$).
Singh et al. (22)	Large effect in favor of exercise SMD = 0.66, 95% CI: 0.52 to 0.80, $p < 0.01$, $I^2 = 90%$; high heterogeneity. Intervention duration had an effect on depression ($\chi^2 = 7.93$, $df = 1$, $p < 0.01$), with interventions lasting longer than 12 weeks producing a large effect (SMD = 0.84, 95% CI: 0.65 to 1.03, $p < 0.01$) and interventions lasting 12 weeks or less having a moderate effect (SMD = 0.44, 95% CI: 0.23 to 0.65, $p < 0.01$).
Song et al. (51)	A fixed-effect model indicated that TCQ significantly reduced depression scores compared to control groups, with an overall medium effect size ($g = -0.457$, 95% CI: -0.795 to -0.118 , $p = 0.008$). Q -value ($p = 0.739$) and I^2 (0%) indicated limited heterogeneity.
Song et al. (40)	Exercise training was able to reduce depression in HD patients (SMD = -0.95 , 95% CI: -1.18 to -0.73 ; $Z = 8.33$, $p < 0.00001$).
Sosa-Reina et al. (42)	There is strong evidence from intention-to-treat and per protocol analysis that exercise reduces symptoms of depression (-0.40 , 95% CI: -0.55 to -0.24 ; $p < 0.001$). Values of Cohen's g suggested that exercise had a small effect on symptoms of depression.
Tu et al. (37)	Strong evidence of a decrease in the symptoms of depression with exercise (SMD -0.38 , 95% CI: -0.55 to -0.21 , $p < 0.00001$) in 3–6 months follow-up.
Vashistha et al. (32)	The pooled data did not reveal a significant improvement in depression (-3.02 , 95%CI: -7.83 to 1.79 , test for overall effect: $Z = 1.23$, $p = 0.22$). Heterogeneity: $\text{Tau}^2 = 9.80$; $\text{Chi}^2 = 4.64$, $df = 1$, $p = 0.03$; $I^2 = 78%$.
Wang et al. (34)	The HAM-D scores of patients performing TCEs improved (MD -3.97 , 95% CI: -5.05 to -2.89 , $p < 0.001$; $I^2 = 0$, $p = 0.91$) compared with those of patients in the control group, based on a random-effects model. The POMS depression scale scores of the patients performing TCEs significantly improved (MD -3.02 , 95% CI: -3.50 to -2.53 , $p < 0.001$; $I^2 = 0%$, $p = 0.76$) compared with those of patients in the control group, based on a random-effects model.
Wayne et al. (30)	The overall effect size based on a random-effects model favors TCQ on depression in cancer patients ($g = -0.27$, 95% CI: -0.44 to -0.11 , $p = 0.001$). A subgroup meta-analysis limited to five RCTs using an active control group showed a statistically non-significant trend toward TCQ improving depression ($g = -0.22$, 95% CI: -0.47 to 0.02 , $p = 0.080$). A subgroup meta-analysis limited to the three RCTs with a no-treatment control group showed a statistically positive effect of TCQ.
Ying et al. (33)	No obvious difference in mitigating depression (SMD = -0.18 , 95% CI: -0.54 to 0.17 , $p = 0.31$).
Zhu et al. (23)	Exercise intervention reduced depression, (SMD = -2.08 , 95% CI: -3.36 to -0.80 , $p = 0.001$, $I^2 = 2%$, $p = 0.41$).
Zhou et al. (45)	Based on the data for depression, there were no significant differences in these parameters between the exercise and control groups (SMD = -0.15 , 95% CI: -0.51 to 0.22 , $p = 0.28$, p for heterogeneity = 0.57, $I^2 = 0%$).

exercise on depressive symptoms in these cohorts (17, 21–23, 55). Different types of interventions were summarized (aerobic, resistance, aerobic and resistance, yoga exercises), with one meta-analysis providing more detailed information about differences between the exercise types: aerobic interventions yielded a large and significant effect on depression at the last follow-up measurement compared with the non-exercising control group (21). Another meta-analysis pointed toward the beneficial effects of an intervention duration of longer than 12 weeks (22).

One meta-analysis only showed little improvement in depression after exercise intervention (20). The two remaining meta-analyses with overlapping populations of Cramer et al.

(18, 19) were heterogeneous. In the 2012 analysis, large short-term effects were shown (19), in the 2017 analysis these results could not be reproduced (18).

Exercise interventions in mixed cancer-samples

Most of these meta-analyses included a majority of breast-cancer patients.

Yoga intervention Buffart et al. showed significant large reductions in depressive symptoms of yoga interventions, one of the included RCTs included lymphoma patients, the other 6 trials breast cancer (25). Lin et al. (29) summarized 6/8 RCTs with breast cancer and different forms of yoga interventions and

showed that depressive symptoms improved significantly in the intervention groups (29).

In the cohort of Wayne et al. breast cancer was also the main disease. The overall effect size favored Thai Chi and QiGong interventions on depressive symptoms (30).

Aerobic or mixed intervention Brown et al. (24) (65% of patients with breast cancer) found a small overall reduction in depressive symptoms of aerobic and yoga interventions compared to standard care among all types of cancer. Subgroup analysis by cancer type revealed significant reductions in depressive symptoms among breast cancer survivors, but no significant difference in depressive symptoms among prostate, leukemia, lymphoma, and colorectal cancer survivors.

Another meta-analysis by Craft et al. revealed modest beneficial effects of exercise (26). Fong et al. evaluated 75% breast cancer patients and showed different outcomes with regard to different depression scales: measured by the BDI, physical activity (aerobic) was associated with reduced depression. Subgroups of four RCTs used the HAMD and POMS scales, the outcomes in this cohort were not significant (27).

In another meta-analysis by Lin et al. (28) with various gynecological cancer-types and various types of activity (i.e., aerobic training, muscle strengthening, stretching exercises or education regarding exercise) no statistically significant improvement could be shown. None of the included RCTs appeared in both analyses (28).

Exercise interventions in Patients with Prostate Cancer

Three meta-analyses were found eligible for this review with regard to prostate cancer. All of them included various types of exercise and one meta-analysis included lifestyle interventions consisting of exercise and other interventions (e.g., dietary advice) (33). The largest meta-analysis with four RCTs found significantly reduced depressive symptoms, while the two smaller ones with 3 RCTs and 2 RCTs found no statistically significant differences (31–33).

Exercise Interventions in Patients With Cardiovascular Disease and Coronary Heart Disease

For cardiovascular diseases, one meta-analysis could be included in our meta-review (34). 4 RCTs summarizing patients with ischemic heart disease or coronary artery disease, cerebrovascular disease, diseases of the aorta and arteries, and peripheral vascular disease compared Thai Chi, qigong, baduanjin interventions to control interventions (e.g., strength training or no intervention). Both outcome measures (HAMD and POMS) showed significant improvements in the intervention groups. One meta-analysis with 2 RCTs/CCTs analyzed the effects of 3-months of Thai Chi Interventions and found positive effects in the intervention group concerning the depressive symptoms (35).

Exercise Interventions in Patients With Heart Failure

The two included meta-analyses showed an improvement in depressive symptoms compared to standard care in large cohorts (36, 37).

Intradialytic Exercise Interventions and Exercise Interventions in Hemodialysis Patients

We could include two meta-analyses for the cohort of intradialytic exercise (38, 39). Exercise interventions included aerobic training, resistance training, or a combination with strength training or range of motion. Both publications showed significant improvements of depressive symptoms (38, 39).

One meta-analysis included intradialytic exercise patients and exercise interventions in hemodialysis patients on non-dialytic days (40). Beneficial effects of exercise were reported.

Exercise Interventions in Patients With Fibromyalgia, Ankylosing Spondylitis and Lupus Erythematoses (LE)

The two cited meta-analyses for fibromyalgia (41, 42) were able to present improved depressive symptoms. The interventions were heterogeneous with Tai Chi and/or Yoga, and/or Qi Gong (41) and aerobic exercise, combined exercise, muscle strengthening, flexibility, stretching (42).

Our search resulted in one meta-analysis that revealed a statistically significant beneficial effect of home-based stretching exercise in reducing depressive symptoms in patients with ankylosing spondylitis (43).

In a meta-analysis of patients with LE, significantly lower depression scores were found in the exercise groups (stretching or aerobic exercise) compared to controls (44).

Exercise Interventions in Patients With Acute Leukemia and Other Hematological Malignancies

Our systematic search resulted in two meta-analyses, one including solely acute leukemia (45) and one including various hematological malignancies (46). Zhou et al. found no significant differences between the exercise (aerobic exercise, mixed-modality exercise) and control groups, whereas Bergenthal showed a statistically significant benefit for the exercise group with aerobic exercise or combined aerobic/strength exercise in a larger cohort.

Exercise Interventions in Patients With HIV

We were able to identify one meta-analysis with a small sample size and various forms of exercise interventions (e.g., walking, jogging, cycling, rowing, stair stepping, and swimming). A significant improvement could be displayed in the depression-dejection sub scale of the POMS d (47).

Exercise Interventions in Patients With Neurological Diseases

Three meta-analyses revealed small but significantly positive effects of exercise on depressive symptoms in multiple sclerosis (16, 48, 49). Different forms of exercise were allowed (Aerobic, Resistance Aerobic+, Yoga).

In Parkinson's disease, exercise interventions (Tai Chi and/or Qigong) led to significantly improved depressive symptoms (51).

Overall, physical exercise resulted in less depressive symptoms in the two suitable meta-analyses of stroke patients (52, 53).

After 10 weeks of follow-up, this beneficial effect could not be maintained (52).

One meta-analysis included various neurological disorders and various exercise interventions. Depressive symptoms were significantly reduced. The effect of exercise on depression was slightly larger in the MS studies compared with the other studies. In addition to the above mentioned neurological disorders (with overlapping single studies), other diseases like Alzheimer's disease, were included (50).

Exercise Interventions in Patients With Traumatic Brain Injury

In one meta-analysis, two RCTs and seven non-RCTs were included and found statistically significant, positive effects of exercise on depressive symptoms (54).

DISCUSSION

We were able to include 39 meta-analyses confirming that the application of exercise as an add-on treatment in patients with somatic disorders is a frequently studied intervention. As stated above, different reasons for this observation can be discussed: the positive effects in depression alone (15), the principle lack of side-effects and the overall improvement of fitness and mortality. In our meta-review, most meta-analyses showed these (expected) beneficial effects of exercise on depressive symptoms (33/39). The six meta-analyses without these effects evaluated different exercise modalities in different types of diseases (18, 20, 28, 32, 33, 45). One of these meta-analyses provided data of breast cancer patients receiving yoga therapy and found no significant effect on depressive symptoms of yoga when comparing to no therapy, but did find significant improvements of depressive symptoms when comparing yoga to psychosocial intervention (7 and 4 included trials) (18). Another meta-analysis with breast-cancer patients found no significant results (20). The smallest of the included meta-analyses with 39 participants (2 trials) also evaluated depressive symptoms in any type of gynecological cancer and found no significant effects (28). Neither of the two meta-analyses with prostate cancer patients nor the meta-analyses with acute lymphoblastic leukemia (ALL) patients found significant reductions in depressive symptoms (32, 33, 45).

Five meta-analyses reported long-term effects with follow-up periods from 3 to 9 months of the exercise interventions (19, 21, 37, 41, 52). The results were heterogeneous with two meta-analyses showing no significant effects in a 3 to 9 months period (19, 52). One meta-analysis only found positive long-term effects during 3 to 6 months for one of the possible exercise interventions in subgroup analyses (41). The two remaining meta-analyses pointed to positive long-term effects in a 3–6 months period (21, 37). In all of these studies except one (37) the follow-up cohort was much smaller compared to the overall sample size. The small sample sizes on the one hand and the small number of meta-analyses in total restrict the generalizability of these results. Future studies should include a follow-up period of at least 3 months (preferably three and 3 months assessments) to accumulate data for meaningful statements.

Following the American College of Sports Medicine (ACSM) guidelines, healthy adults should engage in moderate aerobic exercise training for ≥ 30 min per day on ≥ 5 days per week, vigorous aerobic exercise training for ≥ 20 min per day on ≥ 3 days per week, or a combination of both moderate and vigorous aerobic training. On another 2–3 days, healthy adults should perform resistance exercises for each of the major muscle groups and flexibility exercises for each major muscle-tendon groups on ≥ 2 days per week (56). Future studies should lean on these recommendations to help homogenize the results.

In literature, many different rating scales (self- and observer-rating) have been introduced to assess depressive symptoms, reflecting the variety of questionnaires used in the original trials and the consecutive meta-analyses. For example, the practice guidelines for the treatment of depression in Germany (57) list nine possible questionnaires as valid tools. In specific somatic disorders, validation studies of the most often used scales were performed: HAMD for multiple sclerosis patient (58) and for stroke patients (59). BDI for cancer patients (60) and heart failure patients (61). In a mixed cancer population, a review recommended the CES-D as most precise instrument if depression is the sole focus (62). It has been stated that discrepancies between BDI and HAMD scores (self- and observer rating scales) could be due to different personality traits (e.g., high neuroticism is associated with higher BDI scores) and that therefore both should be regarded separately (63). To date, valid recommendations for all included somatic disorders or general recommendations for specific questionnaires to assess depressive symptoms could not be identified. For future studies, similar outcome measured should be implemented to ensure comparability and both self- and observer rating scales should be combined.

The possible reasons for the varying observations regarding the different intervention types and the measuring time points could be the same reasons that complicate meta-analyses of the existing exercise trials. As stated above, in none of the meta-analyses, the included trials had matching exercise protocols regarding type, duration and frequency of the intervention. Most often no data was provided about the attendance rate of the participants and about the aerobic capacity before/after the intervention as a controlling variable. The quality of the trials ranged from very low to good quality (also with regard to the exercise-specific difficulty of blinding the intervention). In none of the meta-analyses the depressive symptoms after the exercise intervention were the primary endpoint in all of the included trials, so moreover the validity of the conclusions has to be discussed cautiously.

In summary, we were able to identify a large interest in this field of research for the above demonstrated reasons. In most of the meta-analyses, regardless of the underlying somatic disease, beneficial effects of exercise on depressive symptoms could be observed—keeping in mind that depressive symptoms were mainly secondary outcomes in the included studies. Some of the somatic diseases, especially cancer and in this field breast cancer, were overrepresented compared to others like heart failure.

More standardized trials with better comparability are required to draw specific conclusions about the recommended

type and duration of exercise in different diseases. The current findings point to beneficial effects of various forms of exercise, but the implementation in guidelines and for example in therapy strategies that are supported more extensively is still difficult because of the lack of clarity of specific outcomes. Especially the diversity of outcome parameters impedes the comparability of interventions within and between somatic disorders. Moreover, most meta-analyses did not report types of other antidepressant interventions like medication or psychotherapy. Thus, it is difficult to answer the question whether exercise therapy is efficient as an add-on treatment to an ongoing pharmacological or psychotherapy or whether it should be offered as a single intervention in patients with somatic disorders and depression. Finally, information is sparse regarding whether patients continue to exercise after the intervention (e.g., in sport clubs) or whether their overall activity level (e.g., measured by pedometers or more accurately by accelerometers) increases and how this is related to outcome.

CONCLUSION

In this meta-review, we provide an overview of existing evidence for the effects of exercise on depressive symptoms in various somatic disorders. The results are promising, but meaningful recommendations are lacking because of heterogeneous study protocols. For better comparability, we would recommend to implement the following standards in future studies: homogeneous outcome measures, one self-rating scale (e.g., BDI) and one observer-rating scale (e.g., HAMD or MADRS). Moreover, specific information of other antidepressant

treatments (especially medication and psychotherapy) should be consistently reported. State and duration of the somatic disease should be provided. Future studies should lean on recommendation of the ACSM regarding type and intensity of the intervention (e.g., moderate aerobic exercise training for ≥ 30 min per day on ≥ 5 days per week or vigorous aerobic exercise training for ≥ 20 min per day on ≥ 3 days per week; on another 2–3 days, resistance exercises for each of the major muscle groups and flexibility exercises for each major muscle-tendon groups on ≥ 2 days per week) (56). For aerobic training, bicycle ergometers are a widely-used and practical possibility (also for e.g., patients with arthrosis). The duration of the intervention should last at least 12 weeks. Attendance rates, setting (e.g., group activity, with/without supervision) and training intensity should be monitored, preferably with spiroergometric examinations at the start and the end of the study. Follow-up examinations of 3 and 6 months should be performed, and also in this period, information about antidepressant medication should be provided. On these occasions, information about the overall fitness level (e.g., via pedometer/accelerometer measurements over at least 3 days or via activity questionnaires like IPAQ) should be documented.

AUTHOR CONTRIBUTIONS

AR and AH conceived the study. AR and SK performed the qualitative analyses. AR, SK, IM, and AH wrote the first draft. AS and PF supervised the project. BM provided methodological advice; and all authors were involved in the reviewing the manuscript and approved the final version of the manuscript.
