**Background and aims:** The metabolomic profile of a biofluid can be affected by age, and thus provides detailed information about the metabolic alterations in biological processes and reflects the intrinsic rule regulating the growth and developmental processes.

**Methods:** To systemically investigate the characteristics of multiple metabolic profiles associated with canine growth, we analyzed the metabolomics in the plasma and urine samples from 15 young and 15 adult beagle dogs via UHPLC-Q-TOFMS-based metabolomics. Blood routine and serum biochemical analyses were also performed on fasting blood samples.

**Results:** The metabolomics results showed remarkable differences in metabolite fingerprints both in plasma and urine between the young and adult groups. The most obvious age-related metabolite alterations include decreased serum levels of oxoglutaric acid and essential amino acids and derivatives but increased levels of urine levels of O-acetylserine. These changes primarily involved in amino acid metabolism and bile secretion pathways. We also found that the levels of glutamine were consistently higher in both serum and urine of adults, while N-acetylhistamine and uracil concentrations were much lower in the adult group compared to younger ones.

**Conclusion:** Our study provides a whole metabolic profile of serum and urine characteristics of young and adult canines, identifying several metabolites that were significantly associated with age change, which provides theoretical support for the nutrition-related research and age-related homeostasis maintenance in dogs.

## KEYWORDS

metabolomics, growth, plasma, urine, canines

## 1. Introduction

Metabolic homeostasis is a highly dynamic status during the development from juvenile to adult, accompanied by robust changes in physiological metabolites, proteins, cells, and organs. The establishment of metabolic homeostasis is thus closely correlated with and controls nutritional demands, pathophysiologic responses, and disease susceptibilities (1, 2), including atopic diseases, hematological malignancies, autoimmune diseases, diabetes, and cardiovascular diseases (3, 4). Therefore, understanding the growth and age-related molecular mechanisms and metabolic changes is essential for health management and disease prevention.

Metabolomics allows comprehensive detection and analysis of endogenous small molecule compounds in the biological samples, including the substrates, intermediates, and products of metabolic reactions. Since metabolites are the final downstream products in the biological system and contain significant information reflecting age, sex, lifestyle, dietary intake, and disease settings, metabolomics is closer to phenotype than transcriptomics or proteomics (5). Metabolomics has become a powerful tool for unraveling metabolic details and screening important biomarkers of diseases, such as aging, cancer, diabetes, obesity, and cardiovascular disease (6–8).

Currently, most metabonomic studies have demonstrated specific metabonomic characteristics affected by age. For example, Pann et al. found that the plasma metabolomics of mice had high variability at different ages. B6J mice had high levels of acylcarnitines at week 6 and high levels of phenylalanine, ornithine, and tyrosine at week 14 (9). In addition, the histidine/histamine pathway (10), tryptophan, purine, amino acid and nicotinamide metabolism (11), glycine, serine and threonine metabolism, glyoxylic acid, and dicarboxylic acid metabolism pathways in mice are significantly correlated with age (12–15). In a urine metabonomic analysis of healthy children, the researchers found that these significantly age-related metabolites in infancy were amino acid and fatty acid metabolic pathways and carbohydrate metabolism (16). Through metabonomic analysis of plasma and urine samples of young and elderly people, a variety of age-related metabolites were found, such as glutamine, aspartate, glutamate, sphingolipids, trimethylamine N-oxide, etc., mainly involving amino acid and fatty acid metabolic pathways (17, 18). Understanding the metabolic process of the body at different ages and clarifying the role of key metabolites in health, growth and development as well as aging will provide important information for the formulation of nutrition requirements for different stages and anti-aging preventive measures. Furthermore, metabolomics can be further used to investigate the relationship between diseases and age. It has been identified that blood metabolites

and metabolic pathways for PD (Parkinson's Disease) are significantly associated with age, and developed serine as a blood biomarker for the early diagnosis of Parkinson's Disease (PD) (19).

Previous studies have provided strong evidence that metabolomics analysis is an important tool for investigating metabolic changes associated with aging. But comprehensive information about the plasma and urine metabolic networks of dogs and how they are affected by age and other factors is not yet fully understood. With the increasing numbers of pets and evolving of the pet food and medical industry, researchers have focused on the research of healthier pet foods or targeted therapeutic drugs for certain diseases. For example, grain-free pet foods supplemented with methionine, taurine, or methyl donors and methyl receivers can increase the concentration of homocysteine, methionine, or taurine in the plasma after a meal. Supplementing these nutrients can meet the canine's body's demand for amino acids and help to treat diseases that cause metabolic or oxidative stress (20). Dietary calcium fructoborate supplementation can reduce the degree of joint pain in osteoarthritis dogs (21). Therefore, understanding the information about the metabolic alterations in different growth stages could further reveal the mechanisms by which age influences body metabolism and disease risk, and identify the biomarkers with potential clinical utilities, which is vital for formulating nutritional needs at different stages and preventing age-related chronic diseases. In addition, dogs have become a new model of aging biology and age-related diseases. With the growth of age, dogs experience functional decline similar to that of humans, and develop many age-related diseases, including cancer, metabolic syndrome, and neurodegeneration. Therefore, scientific findings on dogs may be helpful to the research on human biology and aging (22, 23).

In our study, an LC-MS-based untargeted metabolomics platform was used to depict the whole alterations of blood and urine metabolomic profiles in dogs of different ages. To reveal the metabolic pathways related to age, we conducted KEGG analysis and correlation analyses on the differential metabolites in the two groups, and finally determined the major age-related metabolites and age-related changes in metabolic pathways, such as amino acid metabolism and bile secretion.

## 2. Materials and methods

### 2.1. Animal

Healthy juvenile beagle puppies ( $n = 15$ , age range = 3–6 months old; mean  $\pm$  SD =  $4 \pm 1$  months) and healthy adult beagle dogs ( $n = 15$ , age range = 12–70 months; mean  $\pm$  SD =  $41 \pm 22$  months) were obtained from Hubei yizhicheng

Biotechnology Co., Ltd. All of the dogs were fed in single cages under the same and stable environmental conditions with temperature at 25°C and relative humidity at 75%. The study protocols were approved by the Ethical Committee of Gannan Medical College.

## 2.2. Collection and preparation of blood and urine

Blood samples were collected *via* blood collection needle from the dog's forearm vein into the BD Vacutainer tubes (BD-Vacutainer; Franklin Lakes, NJ) on the same morning under fasting conditions. EDTA whole blood was analyzed the complete blood count using an VetScan HM5 automatic blood cell analyzer (Abaxis, USA). Blood samples in the heparin anticoagulant tube were centrifuged at 3,000 rpm for 10 min at 4°C to separate plasma. One plasma sample was sent to WellAnimal Test (Wuhan) Co., Ltd. for biochemical detection using an automatic biochemical analyzer (Hitachi 3110; Hitachi, Tokyo, Japan). The remaining plasma was stored at -80 °C freezer until metabolomic analysis.

For urine collection and storage, dogs were anesthetized with a mixture of Zoletil (50 mg/kg) and xylazine (3 mg/kg). Urine was collected by bladder puncture under the direction of a Doppler ultrasonic apparatus. Urine samples were centrifuged at 3,000 rpm for 10 min at 4°C to remove sediments and then stored at -80°C freezers until metabolomic analysis.

## 2.3. Plasma and urine metabolomic analysis

Non-targeted metabolomic analysis of plasma and urine samples was performed using ultra-high performance liquid chromatography (UHPLC; Agilent 1290 Infinity LC System) equipped with Triple TOF 6600 mass spectrometer (AB SCIEX, USA). Chromatographic separation was implemented on Waters, ACQUITY UPLC BEH Amide 1.7 μm, 2.1 × 100 mm column for both positive and negative models. To guarantee the quality of non-targeted metabolomic analysis, 6 QC samples were inserted during metabonomic analysis process. They were slowly thawed at 4 °C, and vortex mixed in pre-cooled extraction buffer (methanol/acetonitrile/water, 2:2:1, v/v). Then, mixtures were sonicated for 30 min at 4 °C, settle for 10 min at -20°C, and centrifuged at 14,000 × g for 20 min at 4°C. The supernatant was collected, vacuum-dried, and resolubilized in 100 μL acetonitrile-water solution (1:1, v/v). The supernatant was separated on UHPLC. The Column temperature was 25 °C, the injection volume was 2 μL and the flow rate was 0.5 mL/min. Then, the samples were analyzed by Triple TOF

6600 mass spectrometers. The ESI parameters were as follows: ion source gas 1 (Gas 1), 60; ion source gas 2 (Gas 2), 60; curtain gas (CUR), 30 psi; source temperature, 600°C; and ion spray voltage floating (ISVF) ± 5,500 V (positive and negative modes). The mass spectrometry data were collected in the Information-dependent acquisition (IDA) mode. The declustering potential (DP) was ±60 V (positive and negative modes); the collision energy (CE) was 35 V with ± 15 eV; Exclude isotopes within 4 Da, and 10 candidate ions were monitored per cycle.

The MS raw data (wiff files) were converted to mzXML format using ProteoWizard, and then peak alignment, retention time correction, and peak area extraction were performed using the R package XCMS program. Based on the self-built database [in-house database (Shanghai Applied Protein Technology)], compound identification of metabolites was performed by matching with the information of the retention time of metabolite, accuracy *m/z* value (<10 ppm), fragmentation analysis, and the identification results were strictly checked and confirmed manually.

## 2.4. Multidimensional statistical analysis

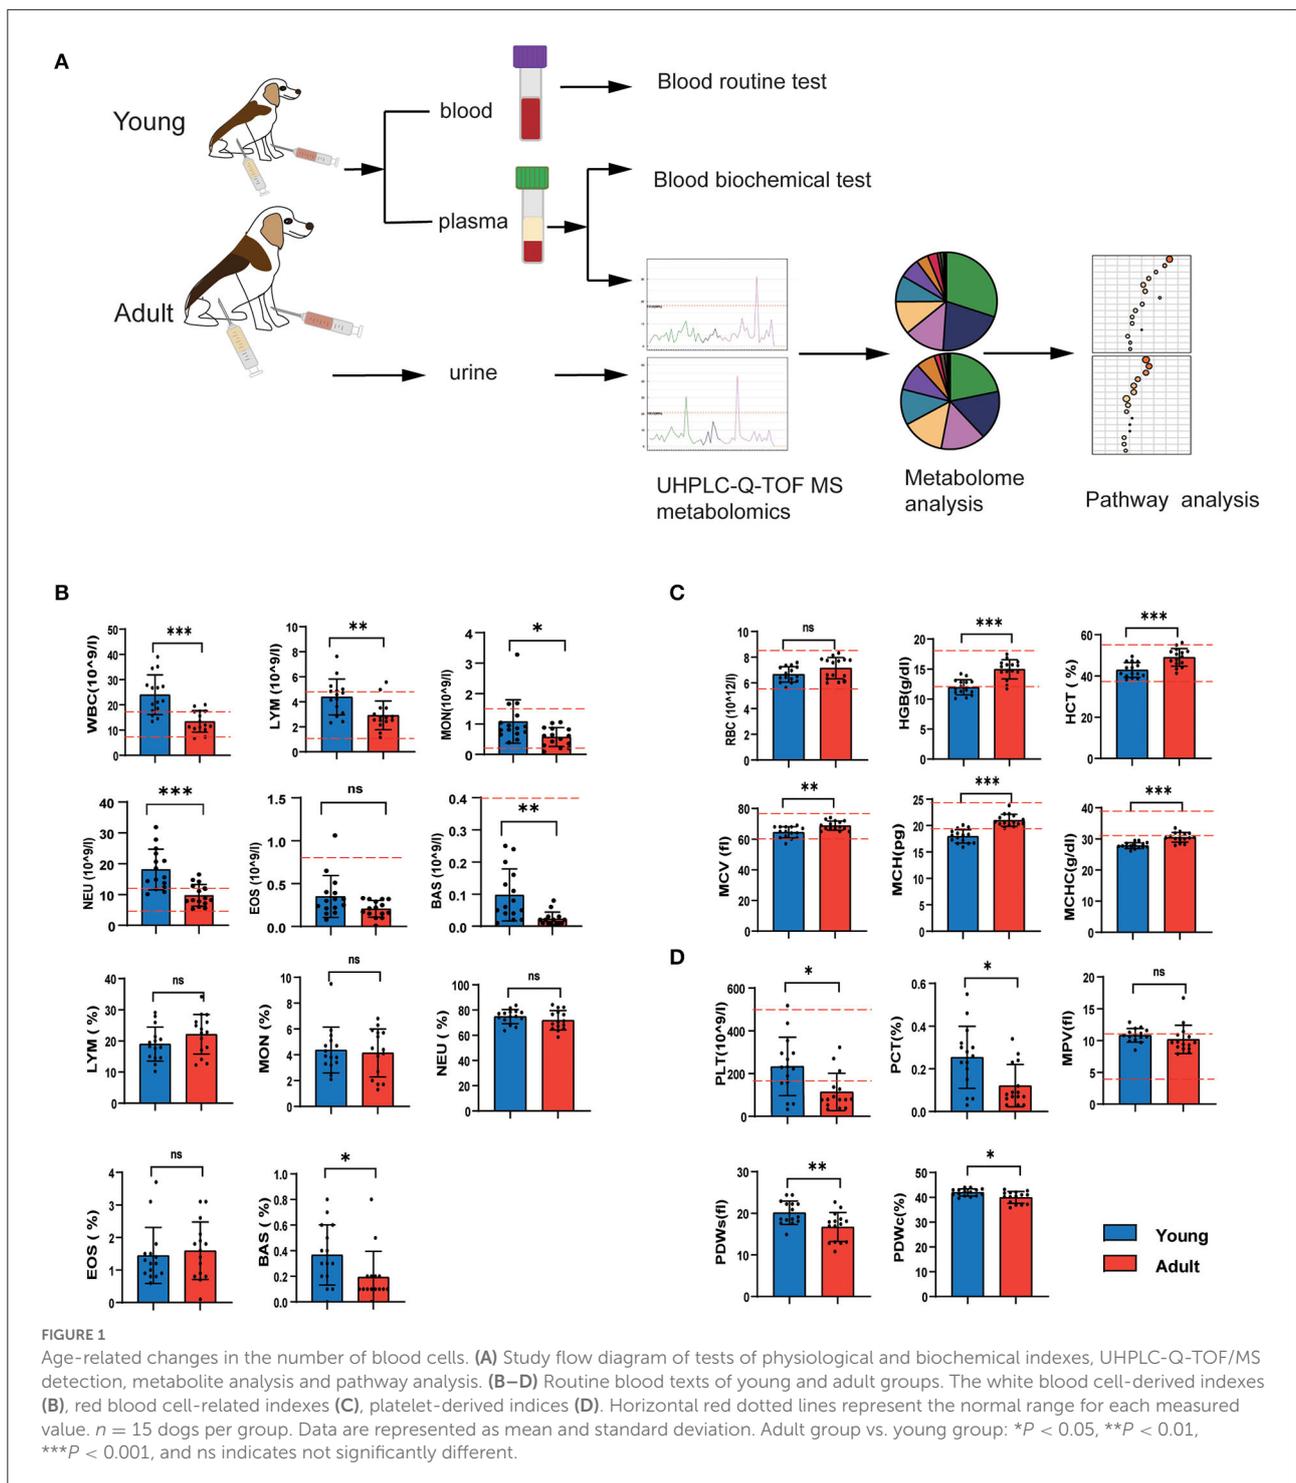

Orthogonal partial least-square discriminant analysis (OPLS-DA) were used for multidimensional statistical analysis. OPLS-DA is a supervised multivariate statistical method and was applied to establish the correlation between metabolites expression and sample as well as to evaluate the variation (R<sup>2</sup><sub>Y</sub>) and predictive ability of the model (Q<sup>2</sup>) by 7-fold cross-validation. The variable importance in projection (VIP) values in the OPLS-DA model (VIP > 1) and *p*-value (*P* < 0.05) were used as the criteria for further screening of significant differential metabolites.

## 2.5. Analysis of pathway and differential metabolites

To identify the most important metabolic pathways during growth and development, the enrichment analysis was performed with KEGG pathway analysis (Kyoto Encyclopedia of Genes and Genomes, <http://www.kegg.jp/>). Correlations between phenotypic and main differential metabolites in plasma, and differential metabolites in plasma and urine were carried out by Spearman's rank correlation.

## 2.6. Statistics

Data were presented as mean ± standard, and 20.0 SPSS (IBM Corporation, Chicago, USA) was used to analyze whether

the data conformed to normal distribution. The two-tailed Student's *t*-test was applied to assess the differences between two groups conforming to normal distribution. If not correspondent with normal distribution, the differences between the two groups was compared using the Mann-Whitney *U* nonparametric test. The level of significance is shown by asterisks: \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ .

### 3. Results

#### 3.1. Age-related changes in the number of blood cells

To investigate the phenotypic variations during canine development, we first collected blood samples that were

subjected to routine blood tests, biochemistry examinations and non-targeted metabolomics (Figure 1A). The results showed that the levels of most routine blood indexes fell within the normal range of established standards for dogs according to the analyzer's software (Figures 1B–D). We found that young dogs had higher levels of leukocyte-related parameters compared with adult dogs, including white blood cell (WBC) counts, lymphocyte (LYM) counts, monocytes (MON) counts, eosinophils (EOS) counts, and neutrophil (NEU) counts, and eosinophil (EOS) (Figure 1B). While the red blood cell-related parameters except red blood cell count (RBC) were much higher in adults as compared to young dogs (Figure 1C). The levels of platelet count were conversely lower in the adult group compared with the younger ones (Figure 1D).

### 3.2. Liver and heart function biomarkers were significantly separated between adult and young canines

As vital biochemical indicators indicating the liver function, the ALT, AST, TP, ALB, and TBIL activities were considerably lower in the young group than those in the adult group ( $p < 0.05$ , Figure 2A). In contrast, the content of plasma myocardial enzymes (LDH, CK, and CK-MB) was significantly decreased along with the development of beagle dogs (Figure 2B). Furthermore, we observed levels of kidney function indexes and blood lipids were largely similar between the two groups (Figures 2C, D). In terms of plasma ions, the calcium, potassium, magnesium, and phosphorus concentrations were much lower in the adult group (Figure 2E), but the fasting blood glucose level in the adult group was higher than younger ones (Figure 2F).

### 3.3. Plasma metabolomics profiles were largely remodeled during canine growth

To deeply investigate the age-related whole changing spectrums in metabolic phenotypes, plasma samples of young dogs and adult dogs were collected and subjected to untargeted metabolomics analysis. A total of 1,498 metabolites were identified in the plasma. As a reliable multivariate statistical method, OPLS-DA was applied to display the differences in metabolites between samples from the two groups. As shown in Figure 3A, the clustering of the young group was well separated from that of the adult group based on the negative and positive ion modes. The model evaluation parameters (for positive ion mode:  $R_2Y = 0.987$ ,  $Q_2Y = 0.893$ ; for negative ion mode:  $R_2Y = 0.993$ ,  $Q_2Y = 0.902$ ) showed that the OPLS-DA model was good in both stability and reliability and can be used for further analysis (Figure 3B).

To identify the age-associated pathway, the KEGG pathway enrichment analysis was carried out according to the differential metabolites ( $VIP > 1$ ,  $P < 0.05$ ), and the top 15 most significantly enriched pathways were shown in Figure 3C. Among them, differentially-expressed metabolites mainly participated in pathways of ABC transporters, alanine, aspartate and glutamate metabolism, arginine biosynthesis, protein digestion and absorption, bile secretion, and histidine metabolism (Figure 3C). The 15 KEGG pathways were further ranked based on their differential abundance scores. Of note, the most significantly decreased pathways included ferroptosis, histidine metabolism, alanine, aspartate and glutamate metabolism, neuroactive ligand-receptor interaction, cholesterol metabolism, arginine biosynthesis, and bile secretion pathway (Figure 3D).

### 3.4. Amino acid and bile metabolism pathways were compromised in adult canines

We comprehensively compared the number of differentially changed metabolites and DA scores of each pathway, and selected four mainly altered metabolic pathways for further analysis, including alanine, aspartate and glutamate metabolism, arginine biosynthesis, bile secretion, and histidine metabolism. For the alanine, aspartate, and glutamate metabolism pathways, we found that the level of L-glutamic acid and oxoglutaric acid were significantly decreased in adult dogs, which lead to reductions in gamma-aminobutyric acid and succinic acid content (Figure 4A). The metabolic map of the arginine biosynthesis reveals that the concentrations of L-arginine, citrulline were significantly decreased, which were associated with low L-glutamic acid and N-acetylornithine levels (Figure 4B). As shown in Figure 4C, the adult dogs had higher plasma cholesterol levels and lower plasma bile acids compared to the young dogs. Particularly, glycocholic acid, taurocholic acid, tauro lithocholic acid 3-sulfate, and taurochenodesoxycholic acid were significantly decreased in the adult group. Figure 4D showed that the degradation products of histidine were significantly decreased with age, such as 1-methylhistidine, N-acetylhistamine, urocanic acid, and 1-methylhistamine, indicating a decrease in histidine metabolism (Figure 4D).

### 3.5. Plasma metabolite profiles were correlated with age-related physiological index

To further explore the physiological significances of plasma differential metabolites, we analyzed the correlations between

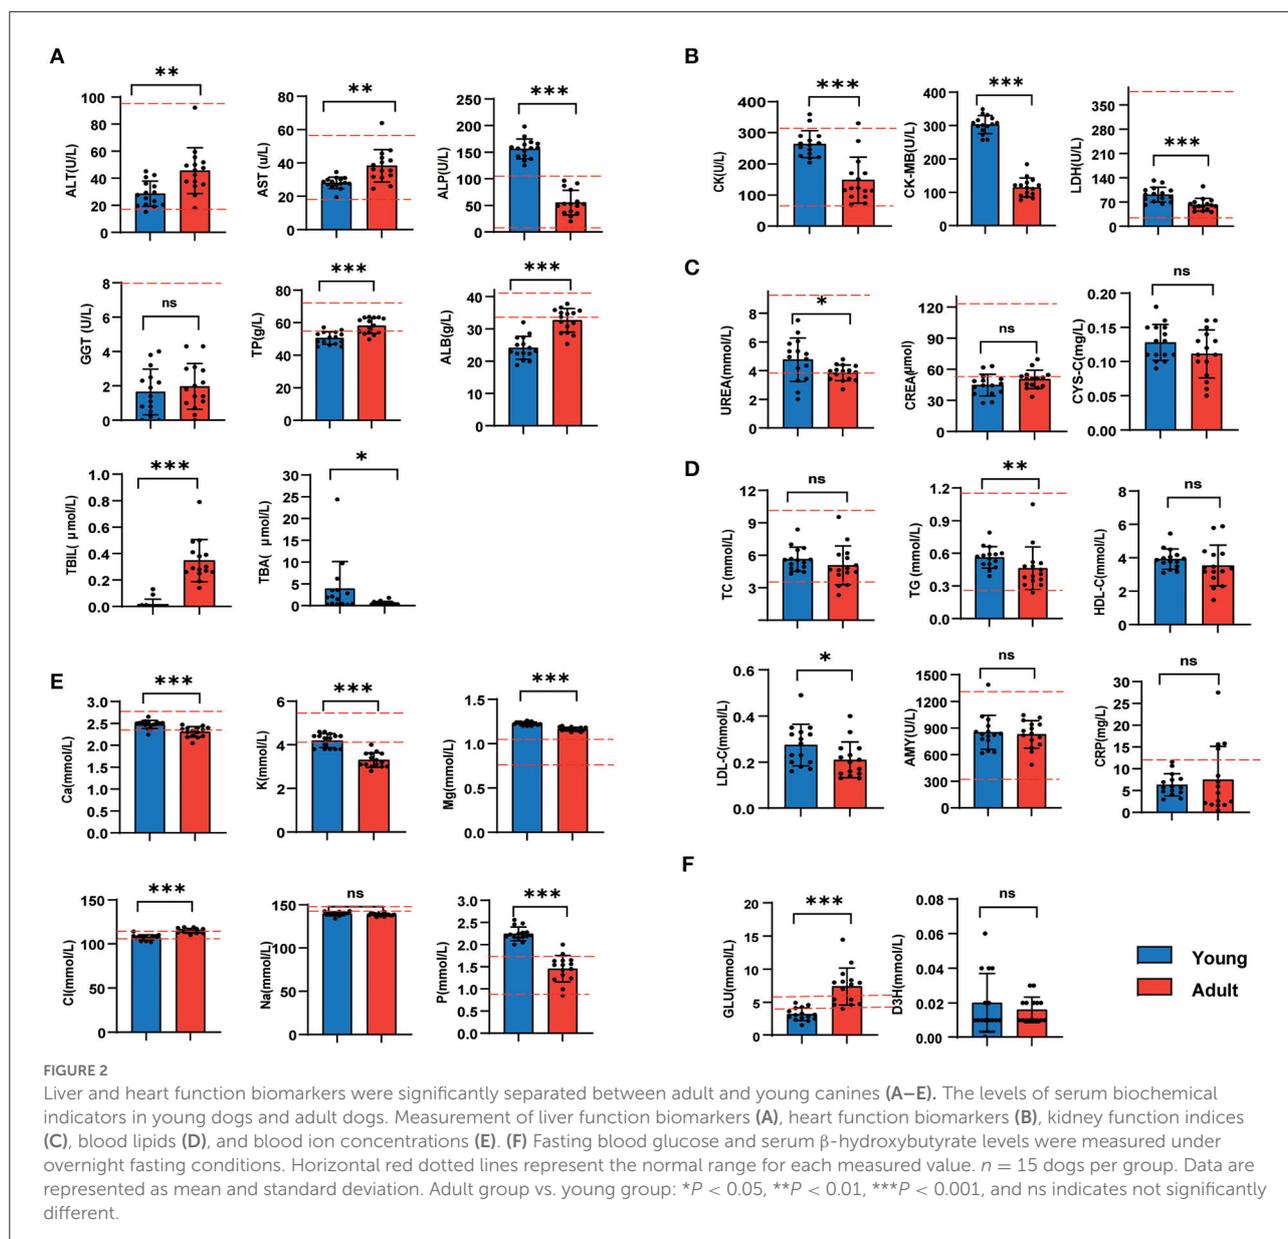

FIGURE 2

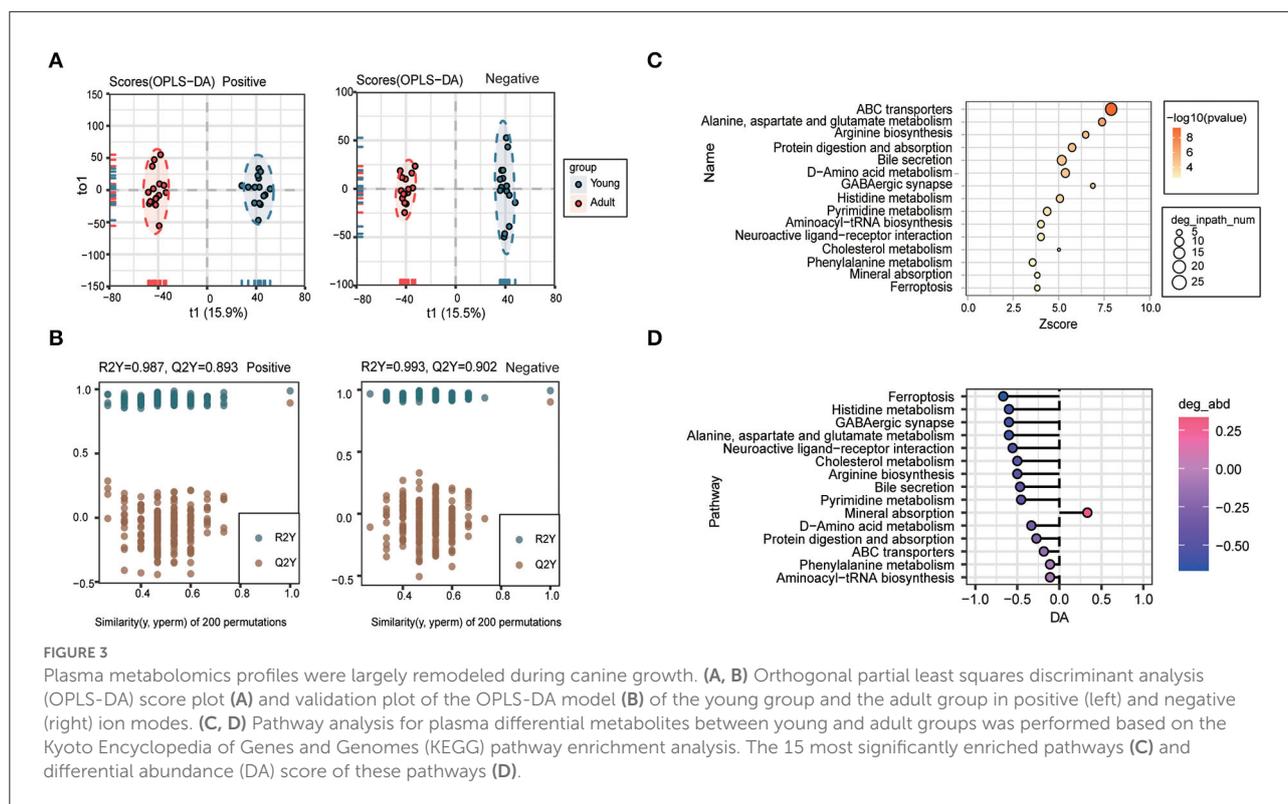

Liver and heart function biomarkers were significantly separated between adult and young canines (A–E). The levels of serum biochemical indicators in young dogs and adult dogs. Measurement of liver function biomarkers (A), heart function biomarkers (B), kidney function indices (C), blood lipids (D), and blood ion concentrations (E). (F) Fasting blood glucose and serum β-hydroxybutyrate levels were measured under overnight fasting conditions. Horizontal red dotted lines represent the normal range for each measured value.  $n = 15$  dogs per group. Data are represented as mean and standard deviation. Adult group vs. young group: \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , and ns indicates not significantly different.

the level of dramatically changed metabolites with that of routine blood and biochemical indexes (Figure 5). The results showed that the gamma-aminobutyric acid, oxoglutaric acid, succinic acid, taurocholic acid, 1-methylhistidine, and 1-methylhistamine were positively correlated with WBC, NEU, BAS, PLT, and PCT. The gamma-aminobutyric acid, glycocholic acid, 1-methylhistidine, 1-methylhistamine, and carnosine were positively correlated with CK, CK-MB, LDH, and ALP but negatively correlated with ALT, AST, TBIL, and ALB. As shown in Figure 5D, the differential metabolites in the histidine metabolism pathway were the strongest ones correlated with both blood cell counts and organ heart functional indexes.

### 3.6. Urine metabolite profile undergone significantly change during body growth

Since urine metabolic profile is closely correlated with body development and physiological status, we further carried out urine metabolomics assay using UHPLC-Q-TOF MS in both positive and negative ion scan modes. The OPLS-DA model showed a clear cluster differentiation of the metabolic profiles between the young and adult groups (Figure 6A) with satisfactory evaluation indexes reflecting a high stability of the model (Figure 6B).

A total of 600 differential metabolites were identified and mapped into 32 KEGG pathways, and the 15 most

significantly enriched pathways were shown in Figure 6C, mainly including bile secretion, neuroactive ligand-receptor interaction, protein digestion and absorption, glycine, serine and threonine metabolism, and other metabolic processes. Clearly, we noted that cholinergic synapse, bile secretion, sulfur relay system, taste transduction, cysteine and methionine metabolism pathways were significantly upregulated in the adult group, while the pentose phosphate pathway as well as protein digestion and absorption pathways were largely inactivated along with body growth (Figure 6D). Among metabolites involved in those enriched pathways, O-acetylserine, morphine-6-glucuronide, and L-cysteine were identified as the most significantly changed ones in the urine samples from adult animals compared to the younger ones (Figure 6E).

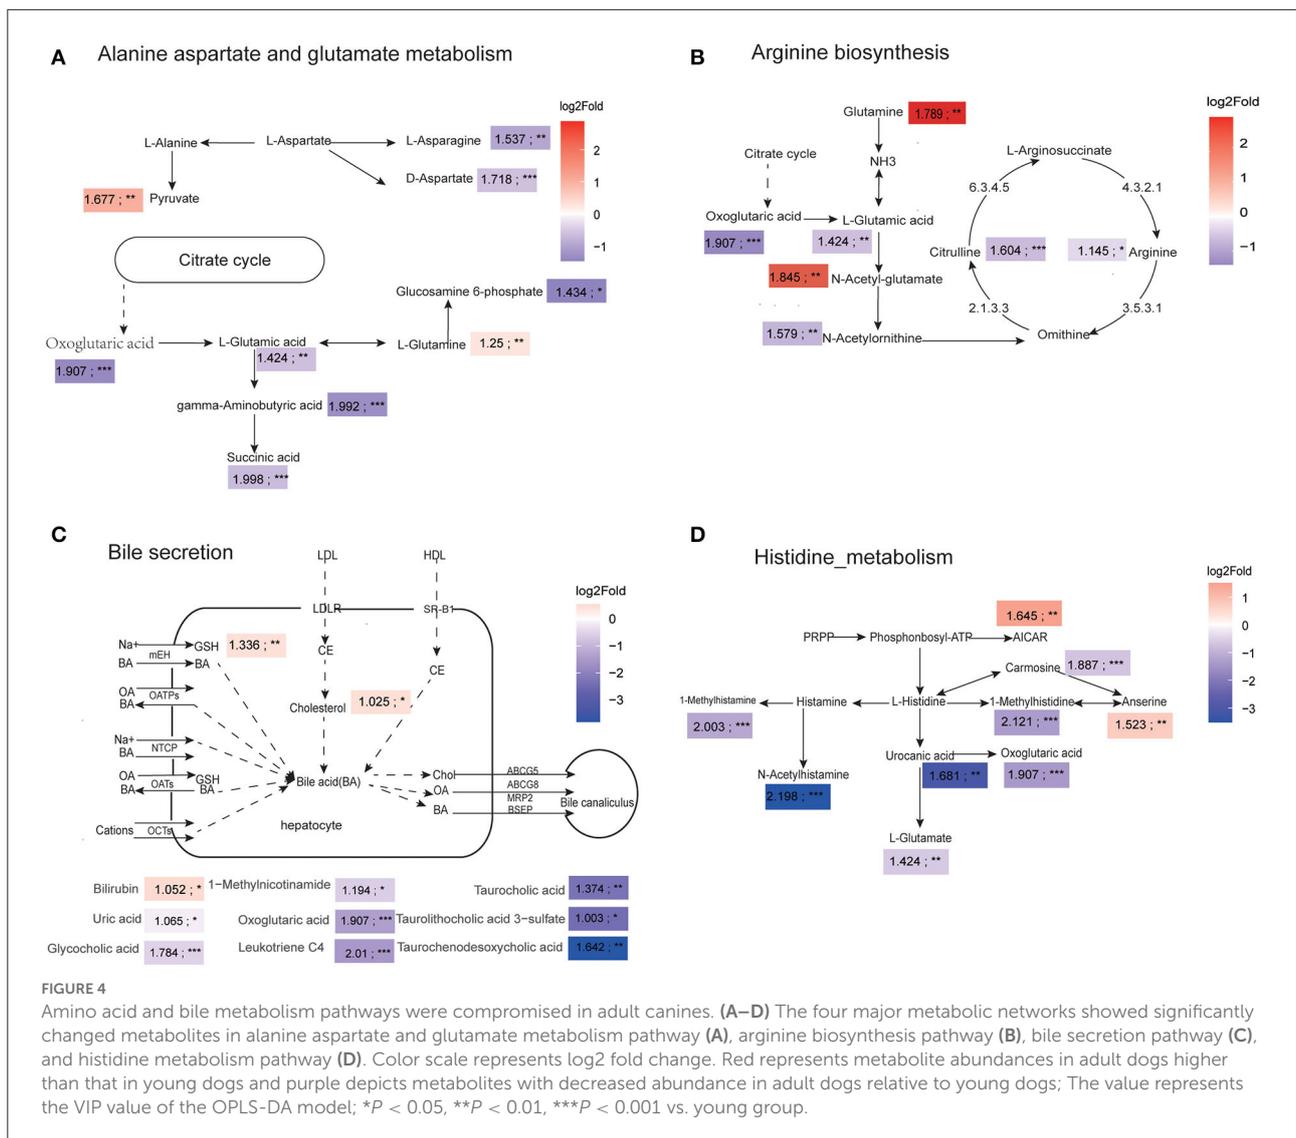

### 3.7. Amino acids and their derivatives were conserved metabolites reflecting development in both plasma and urine

Our combined metabolomics analysis revealed that 745 metabolites were identified in both the plasma and urine samples (Figure 7A), among which 9 conserved differential metabolites were identified (Figures 7B, C). Notably, glutamine, methylmalonic acid and L-carnitine were all significantly higher in adult body fluid samples than those in young group

(Figure 7D). In contrary, the abundance of 6 metabolites, such as N-acetylhistamine and uracil, were much lower in both the plasma and urine of adult ones (Figure 7D). These conserved metabolites were related to 11 KEGG pathways, in particular pyrimidine metabolism and ABC transporters pathways (Figure 7D).

## 4. Discussion

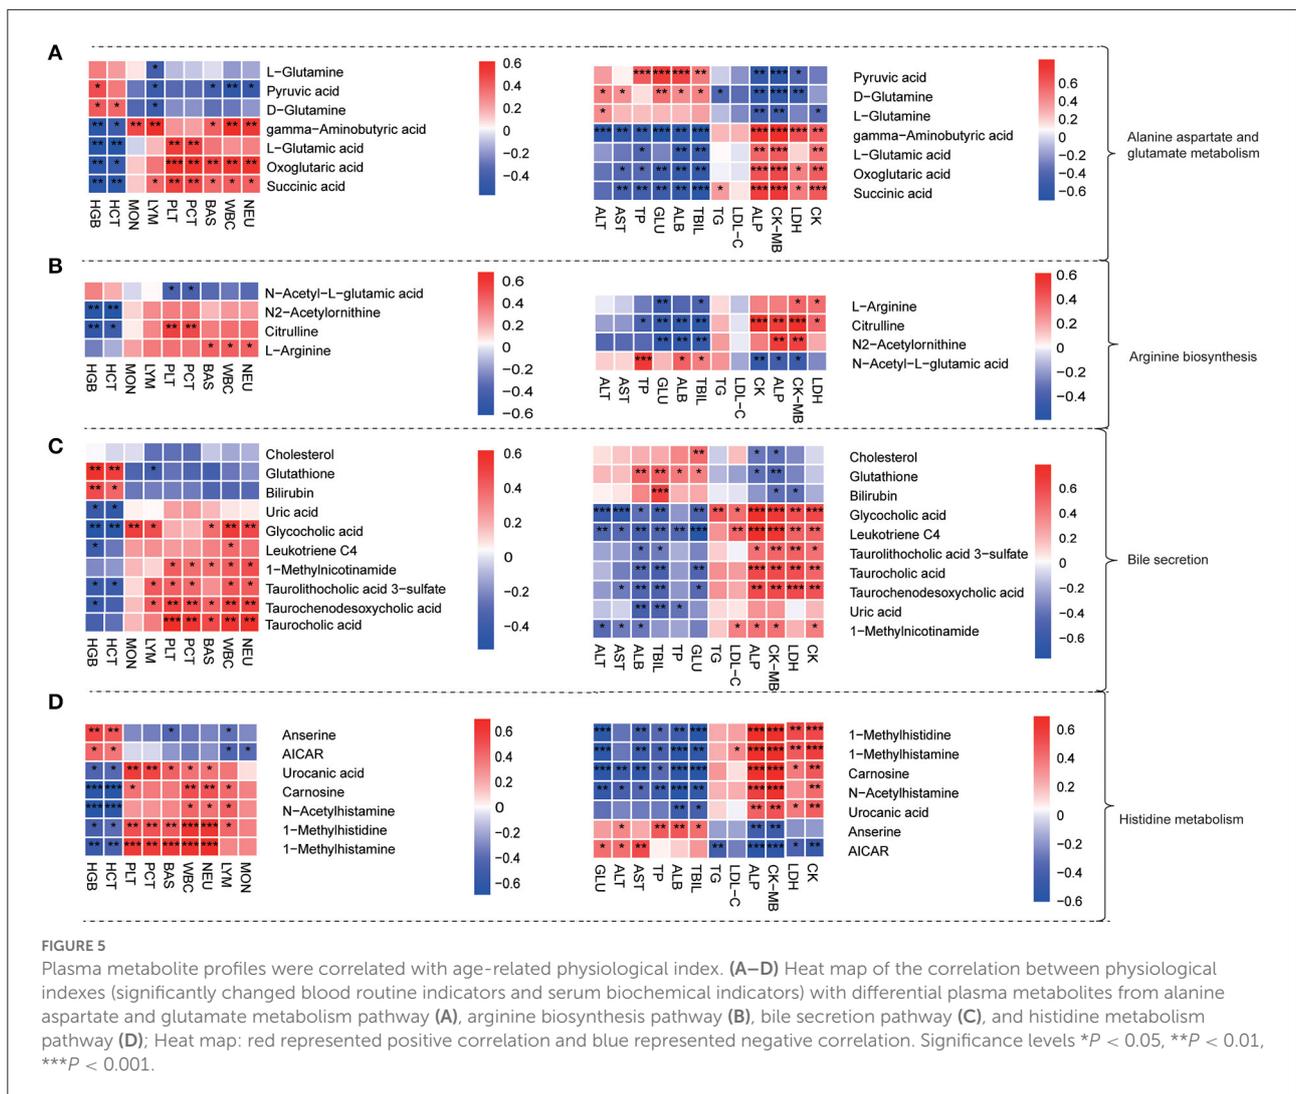

Age is one of the main factors affecting physiology and metabolic changes. In the present study, the age-related phenotypic variations were evidenced by blood routine, serum biochemical tests, and plasma and urine metabolites. In terms of blood routine tests, we observed higher levels of WBC and PLT but lower RBC levels in young dogs than that in adults. The age-associated changes in hematological reported in this study are consistent with those findings in dogs reported in previous studies (24, 25). Brenten T et al. regularly collected the blood of Labrador retriever and miniature schnauzer dogs between weeks 8 and 52 for blood routine and blood biochemical analysis, and found that WBC count decreased over time, RBC, HGB, HCT, MCV, and MCH increased with age (26). Ishii T et al. compared the blood routine data from juvenile beagle dogs (<3 months of age) with dogs (6 months of age) and found that the count of RBC increased and WBC decreased with the growth of beagles

(27). RBC maturation and HGB concentration were positively correlated with age (28, 29).

Blood biochemistry is a useful diagnostic tool to assess organ system health. It is necessary to understand the age-related changes in blood chemistry. In this study, AST and ALT activities were significantly higher in the adult group than those in the young group, The effect of age on ALT and AST activity is consistent with prior results. Ishii T et al. analyzed the different of blood chemistry data between the two age classes, and found that the growth of beagle dogs was shown to be associated with increases in AST, ALT, and with decreases in CK (27). ALT is primarily localized in the liver, while AST is expressed in liver, cardiac muscle, and skeletal muscle. All of them are important enzymes in the liver and are involved in the formation of oxalacetic and pyruvic acids respectively. Serum AST and ALT levels increased with age, which is closely related to tissue

growth and muscle mass (26). When the metabolism of liver cells or muscle cells in the body is enhanced, the intracellular transaminase enters the serum after cell rupture, resulting in the increase of AST and ALT concentrations in plasma. In addition, the activities of ALT and AST in serum are important indicators to evaluate the extent of hepatic injury (30). Early studies identified that increased AST and ALT levels in aged mice suggest impairment of the liver and metabolic syndrome (31–33). Conversely, higher serum ALP levels were observed in young dogs, which might be due to the production of bone-specific ALP, an ALP isoenzyme, elevating as a result of skeletal growth and increased osteoblastic activity (34, 35). In addition, due to physiological differences between young and adult dogs, some indicators of young dogs were not within the normal range of blood routine or blood biochemical indexes for adult dogs (Figures 1, 2). Therefore, it is very important to identify

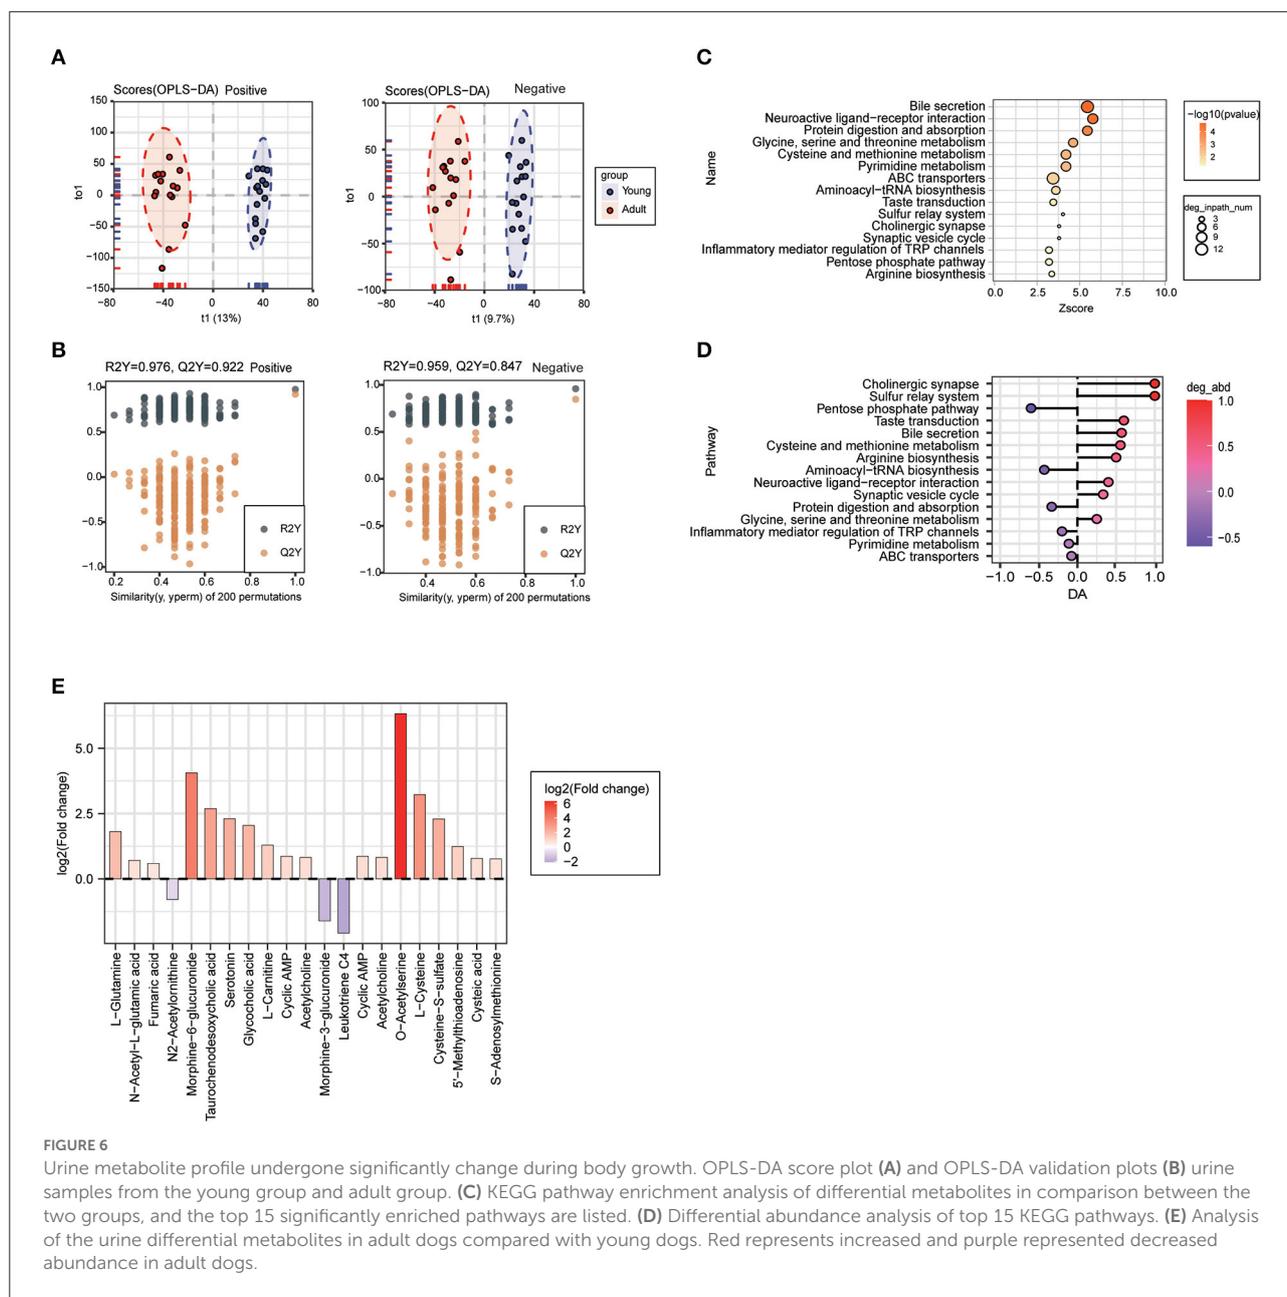

the changes of age-related physiological indicators and establish reference intervals for blood routine and biochemical indicators in dogs of different ages.

Regarding the metabolomics profiles, several pathways were significantly different between young and adult dogs, mainly including amino acid metabolism (alanine aspartate and glutamate metabolism, arginine biosynthesis, histidine metabolism), bile secretion, and cholesterol metabolism. In particular, the levels of oxoglutaric acid, gamma-aminobutyric acid, L-Glutamic, D-Aspartate and succinic acid were decreased in adult dogs compared to young dogs. These metabolome characteristics of dogs showed high similarity to those in human studies (12). As a key intermediate of the tricarboxylic acid (TCA) cycle, oxoglutaric acid is a significant regulatory metabolite that coordinates nitrogen and carbon metabolism, which has the physiological function of regulating nitrogen metabolism, energy metabolism, maintaining intestinal health, and improving bone (36). The

basal diet supplemented with oxoglutaric acid can improve the glutamine metabolism of intestinal cells, enhance intestinal digestion and absorption function, and improve the bone mineral density and performance of piglets (37, 38). In addition, oxoglutaric acid is a biosynthetic precursor of many amino acids such as L-glutamic acid, L-glutamine, succinic acid, and L-arginine acid (39). Glutamic acid is an important neurotransmitter in the central nervous system. It can be catalyzed by glutamic acid decarboxylase (GAD) to produce Gamma-aminobutyric acid (GABA), which is also a well-known neurotransmitter (40, 41). Roalf DR et al. found lower levels of brain Glu in healthy older adults compared to younger adults, leading to age-related declines in behavioral and cognitive function, indicating changes in glutamate as a marker for age-related neurological changes (42).

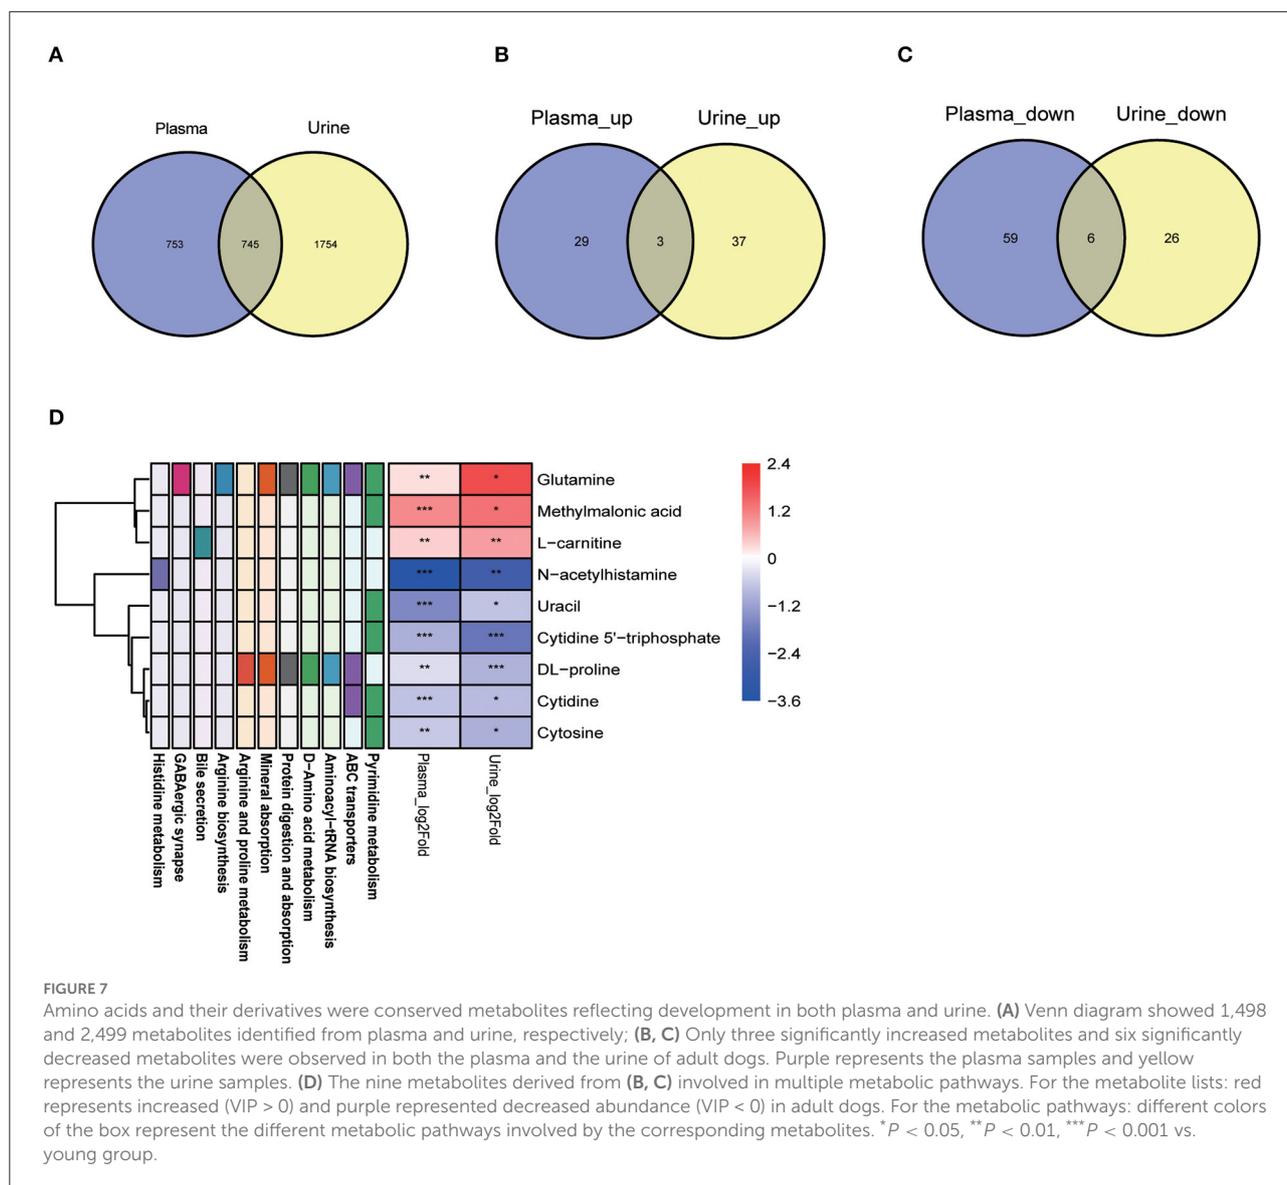

Blood arginine levels are maintained by food protein, protein turnover, and endogenous synthesis from citrulline

**FIGURE 6** Urine metabolite profile undergone significantly change during body growth. OPLS-DA score plot (A) and OPLS-DA validation plots (B) urine samples from the young group and adult group. (C) KEGG pathway enrichment analysis of differential metabolites in comparison between the two groups, and the top 15 significantly enriched pathways are listed. (D) Differential abundance analysis of top 15 KEGG pathways. (E) Analysis of the urine differential metabolites in adult dogs compared with young dogs. Red represents increased and purple represented decreased abundance in adult dogs.

through the small intestine-kidney metabolic axis (43). High plasma citrulline concentration in neonates and neonatal pigs was utilized by the kidney for arginine synthesis *via* the intestinal-renal axis (44). The arginine biosynthesis pathway was inhibited in adult dogs, which may due to inhibition of the absorption in the intestine or *de novo* synthesis of arginine (45). Arginine, the precursor for the production of intracellular NO, involved in the regulation of vascular tone and immune regulation, improving cardiovascular function in hypertension and pulmonary hypertension (46). Exogenous supplement of arginine can increase the synthesis and release

of NO, and has significant effects on enhancing blood flow, lowering blood pressure and improving arteriosclerosis. L-citrulline is precursor of L-arginine, which more effective and bioavailable because it has a longer circulation time (46). Clinical studies showed that arginine supplementation, in the form of either arginine or citrulline, can improve pulmonary hemodynamics and blood circulation in the cerebral microvasculature, have therapeutic benefits in children with MELAS syndrome (47–49). In addition, arginine is involved in the body’s protein composition, and lack of arginine in young animals will lead to delayed production and reduced

immunity. It has been found that adding arginine to the feed of piglets can improve immune status and growth performance (50, 51).

Histidine pathway analyses revealed that the plasma levels of 1-methylhistidine, 1-methylhistamine, urocanic acid, and N-acetylhistamine in the young dogs were significantly higher than those in adult dogs, indicating that active histidine metabolism in young dog. Histidine is a dietary essential amino acid with unique roles in the scavenging of reactive oxygen and nitrogen species, erythropoiesis, and the histaminergic system (52, 53). At present, histidine has been used as a nutritional supplement under various conditions. histidine can improve the gastric mucosal damage induced by aspirin in rats (54). Combined use of histidine and vitamin C can

reduce free radical induced toxicity, and prevent isoproterenol-induced cardiotoxicity (55). It can also inhibit inflammation and oxidative stress, enhance skin barrier function, and reduce the severity of AD (56). In addition, L-histidine combines with beta-alanine to synthesize the carnosine, which is widely abundant in skeletal muscle, heart, and brain tissues. Carnosine has the function of anti-oxidant, free-radical scavenging and exercise performance-enhancing. The level of carnosine is associated with gender and age, and decreased with age (57, 58). This study found that carnosine levels in dogs showed the same trend.

Compared with younger plasma, adult canines possess lower taurocholic acid and some bile acid abundances but higher cholesterol concentration in adult plasma samples.

Bile acid, an important solution for digesting fats, is metabolized from cholesterol in the liver and secreted into the duodenum for digestion and absorption of ingested lipids and fat-soluble vitamins (59). In earlier studies of the human gallstone disease, Kim et al. (60) have found that the liver synthesis of primary bile acid was decreased and the cholesterol secretion was enhanced with age, further increasing the cholesterol saturation of bile, resulting in an increased probability of developing gallstones. Han et al. showed that the decrease in bile acid synthesis and secretion was associated with liver aging by transplanting livers of young rats into old rats (61). Additionally, lowered bile acid secretion was unfavorable for anti-allergic and anticarcinogenic (62). Recent studies indicate that certain probiotic supplementation, such as Bifidobacteria, could reduce cholesterol levels *via* converting cholesterol into the cell membrane of probiotics (59).

Analyzing urine metabolites between young and adult dogs, we found that the bile secretion pathway was the remarkably enriched KEGG pathway. The urine of adult dogs was characterized by the higher content of O-acetylserine, morphine-6-glucuronide, and L-cysteine, and the lower content of leukotriene C4. O-acetylserine is a central metabolite of sulfur assimilation, providing the carbon backbone for catalyzing cysteine formation (63). Cysteine can be directly taken off sulfhydryl and amino to generate pyruvate, which can form acetyl-CoA through oxidative decarboxylation, and then be further converted to glutamate (64, 65). Cysteine, as a glutathione precursor, has antioxidant potential. N-acetylcysteine and cysteine-rich whey protein isolate are usually used as cysteine supplements in clinical studies. N-acetylcysteine was shown to increase whole blood glutathione levels and decrease the basal insulin reactivity in AIDS patients and non-diabetic obese patients, respectively (66, 67). Additionally, cysteine-rich undenatured whey protein could significantly improve the skeletal muscle function, decreased plasma levels of the inflammatory cytokine tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), improved immune functions, and increased plasma albumin levels (68).

In conclusion, the present study systematically profiled the phenotypic and metabolic characteristics of young and adult beagle dogs. Our findings showed apparent variations in blood routine and biochemical indexes, and, more importantly, supported a dramatic metabolite remodeling in body fluids during canine growth. In recent years, the addition of functional ingredients in food is becoming a new direction of pet foods research and development to fulfill the specific requirements for the growth and improve the organismal fitness (21, 69). Analyzing the dynamic metabolic process could firmly guide food research and development and disease therapy.

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary material](#), further inquiries can be directed to the corresponding authors.

## Ethics statement

The animal study was reviewed and approved by the Animal Ethics Committee of the Gannan Medical University.

## Author contributions

JW, X-JZ, YC, and HL designed the research. TW, MY, and SW performed the research and acquired the data. XW, XC, YH, and YD analyzed the data. X-JZ, YC, TW, MY, MH, and XZ wrote the manuscript. All authors were involved in revising the manuscript and approved the final version before submission.

## Funding

This research was funded by grants from the National Science Foundation of China, grant numbers 82170595 and 81970070 and the Hubei Province Innovation Platform Construction Project, grant number 20204201117303072238.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.

## Supplementary material

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fvets.2022.1037327/full#supplementary-material>
